The most cursory inspection shows that in such a course none of the professional studies of the medical course is undertaken. There is no attempt to anticipate them, but there is insistence placed upon certain subjects knowledge of which and skill in which are evidently of the highest value in the work of the medical college. It will also be seen that such a course as I have sketched in the broadest lines has two main objects in view: First, to give to the pre-medical student the broad vision and strong mental grasp that can result only from a broad and liberal culture. Second, to give such special training in those subjects which underlie the science of medicine, that he may, when he enters the professional school, be prepared for its real problems and in a much greater degree than at present understand the magnitude of the work he has undertaken when he has chosen to enter the ranks of the medical profession. Incidentally this method saves one of the preparation years, no small matter in these strenuous times.

If the professional school of medicine and the college could make satisfactory allotment of courses more or less common to both, time and money and strength would be saved and much good would be done for medical science and through it for humanity.

THE CHEST PANTOGRAPH AND THE MAXOMETER—THEIR CLINICAL USE AND VALUE.*

By C. B. VAN ZANT, M.D.
DENVER, COLORADO.
PROFESSOR OF PHYSIOLOGY AT THE GROSS MEDICAL COLLEGE.

Any device which will aid the physician not only in the diagnosis and treatment, but also in the proper recording of certain phases of his cases, has a claim on the interest of the body of medical men such as this. I desire, therefore, to present two instruments of precision, which have a limited range of usefulness, but which admirably meet the necessities of a certain class of cases.

First, as to the instrument, the chest pantograph. It is a device originated, I believe, by Prof. W. S. Hall of the Northwestern Medical School of Chicago

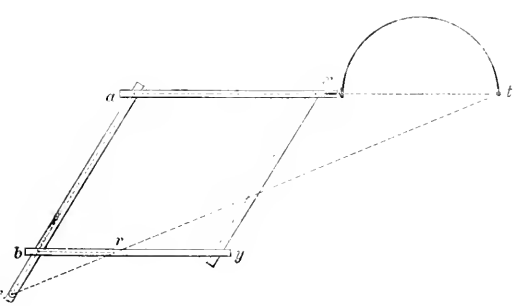

Fig. 1.—The Chest Pantograph. (From Hall's Text-Book of Physiology.)

for purely physiological purposes, namely, the graphic recording of the contour of the chest-wall and the determination of the cross-sectional area of the chest, at the end of both inspiration and expiration. This instrument is but a modification of the ordinary pantograph used by the artist in enlarging or reducing a picture. The position of the pencil is such that the outline of the chest, as recorded on the chart, may be made one-fourth or one-fifth of the actual size. In its use, the patient is placed at the side of a table with the chest level, to be depicted, opposite the top of the table. A sheet of ordinary paper, ruled off in squares a millimeter in size, is fastened to the table by thumb tacks, and the pantograph is then clamped to the table. By drawing the end of the brass semicircle around the chest, starting and stopping at the same point, the chest contour will be perfectly duplicated on the paper. The advantage of the ruled paper is that it enables one accurately to calculate any diameter, or the cross-sectional area, of the chest. In the tracing of the normal chest, you will notice the larger dimensions of the right half of the thorax, due, doubtless, to its better muscular development in right-handed persons.

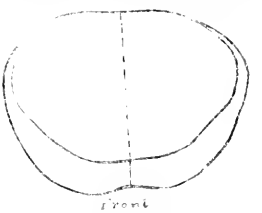

Fig. 2.—Contour of the Normal Chest.

Now, it has occurred to me that, while the instrument was gotten up purely as a physiological device, it is capable of considerable practical clinical utility, in estimating and recording certain diseased conditions. Among these the following suggest themselves as appropriate for its use:

1. By *inspection*, in a case of pulmonary tuberculosis, we make a crude estimate of the chest form and say, "there is *some* depression" in one infraclavicular region; or "there is *deficient* expansion" on one side. With the exception of the cyrtometer

Fig. 3.—Tuberculosis of the Right Apex mainly. Contour of the infraclavicular regions, from one coracoid process to the other.

Fig. 4.—Tuberculosis of the Right Apex. Contour of the infraclavicular regions, from one coracoid process to the other.

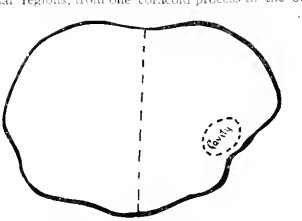

Fig. 5.—Disease on Both Sides, but Chiefly on the Left. There is a cavity with fibroid contraction at the left apex.

of Voillex, which makes a cumbersome, full-sized tracing, there is no accurate method of recording this alteration in the shape of the depressed region or of recording the *amount* of the defect in ex-

* Read before the Colorado State Medical Society, June 20, 1901.

pansion, in inspiration, at a given examination. With the pantograph, or stethogoniometer as it is often called, a reduced tracing can be made and preserved; and subsequently any increase in the condition and its amount can be determined by another

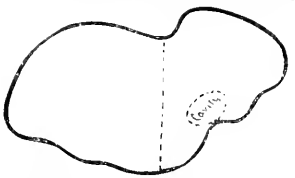

FIG. 6.—Trouble on the Left Side mainly. The chest-wall has fallen in over a cavity as a result of a resection of the overlying ribs.

tracing. In this way we can scientifically note the progress of these features of our cases of pulmonary disease.

2. What has just been said will apply with equal force to *any* deformity of the chest, *progressive* in character, such as that of emphysema, of contraction of the chest, following pleurisy or incident to fibroid disease of the lung, or that occurring in curvatures of the spine (anterior, posterior, or lateral); to intra-thoracic tumors, aneurysmal or otherwise, pressing out the chest-wall at any point; to precordial bulging from pericardial effusion, especially in children, or to distention of one side of the chest by liquid or air in the pleural cavity.

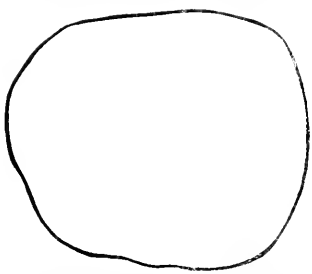

FIG. 7.—Emphysema in a Person Sixty-nine Years of Age. The right side is smaller than the left at the end of inspiration, because it is filled with pleuritic effusion.

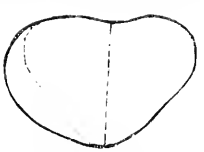

FIG. 8.—From a Girl, Twelve Years of Age. Left side retracted by pleurisy.

3. As a means of record, purely, in *unprogressive* deformities of the chest, it is also of value. Take, for instance, its tracing of pigeon-breast, funnel-breast, the rachitic chest, the alar chest, the barrel-shaped chest, etc.

4. As a definite means of keeping track of many conditions beside those of the thorax, surgical as well as medical, the pantograph is available. Thus we could record the change in size and shape of the face in acromegaly, of the head in hydrocephalus, of the neck in goiter, of the abdomen in cases of irregular tumors and enlargement, where mensuration would not suffice, in the extremities, in certain

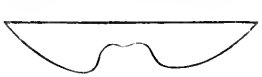

FIG. 9.—Alar Chest. Back tracing, showing the projection of the scapulæ; same patient as in Fig. 4.

FIG. 10.—Fourteen Years of Age. Pigeon breast

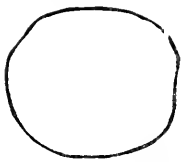

FIG. 11.—Six Years Old. Rachitic chest.

malformations, tumors, etc. Illustrative of its work, a number of tracings are herewith presented.

The second appliance, of which I desire to present the claims, is the ordinary manometer filled with mercury or with physiological salt solution. It consists of a U-shaped tube, containing the selected fluid. To this a rubber tube is attached, through which the pressure of fluid or gas can be brought to bear upon the column of liquid. This pressure causes the fluid to rise in the near or far limb of the manometer according as the pressure is negative or positive. Clinically, this instrument has been used for years in estimating expiratory pressure. Of this, however, I do not desire to speak, but rather of a new field of usefulness in the surgery of the chest. To enable me better to present its value in that field, you will pardon a word on the physiology of the pleura. As you are well aware, by virtue of the elasticity of the lung parenchyma, there is a constant tendency for the lung to pull away from the chest-wall, that is, a tendency to a separation of the pulmonary and costal layers of the pleura. Normally this cannot be accomplished; nevertheless, the elastic pull is there, and leads to a constant condition of negative pressure, or "suction" if you prefer, in the pleural cavity, known as the intra-pleural or intra-thoracic pressure. Its amount is six millimeters of mercury at the end of expiration and nine millimeters at the end of inspiration. If after connecting it with a manometer, you insert a small hollow needle carefully through the chest-wall, the moment it enters the pleural cavity the suction there leads to a movement of the mercury in the manometer toward the pleura. If, through disease, the layers of the pleura are adherent, the pleural cavity is thereby obliterated, and its negative pressure is annulled. Under these circumstances there will be no movement of the fluid toward the chest. Thus the manometer affords an easy and safe method of disclosing the presence or absence of pleural adhesions in any case. To Sapiejko belongs much credit for introducing this simple method of procedure. Its value will be apparent when you consider the present status of lung and chest surgery. To-day, abscesses of the lung are being directly opened; gangrenous, tuberculous, and actinomycotic foci in the lung are being excised; cavities, tuberculous and bronchiec-

tatic, are being opened and drained or topically treated. Much success has attended the direct treatment of these tuberculous cavities and lung abscesses. In an article in the *Revue de Chirurgie*, July 10, 1899, Sapiejko concludes from a considerable experience in lung surgery that incision of the pleura and lung may lead to a favorable issue, if pleural adhesions exist; and, fortunately, these are present in the majority of cases in which suppurative processes occur in the lungs. It is, therefore, of the highest importance to determine whether adhesions *do* exist and their exact situation, so that the shortest and least dangerous route through them to the focus of lung disease can be determined. This the manometer readily accomplishes. Moreover, where no adhesions exist, the instrument gives instant warning of the penetration of the costal pleura and prevents unnecessary penetration of the lung.

In cases in which it is desired to use Murphy's artificial pneumothorax method for the treatment of pulmonary tuberculosis, the presence of firm adhesions is prohibitive, and here the manometer gives valuable preliminary information. By many observers it is coming to be believed that in pulmonary hemorrhage the intra-pleural injection of air or of nitrogen to compress the bleeding lung is a very valuable resource. Henry P. Loomis (MEDICAL RECORD, May 19, 1899) says that it has never failed in his experience to stop pulmonary hemorrhage, even in desperate cases. Stubbert and C. P. Thomas give similar testimony (*Journal of the American Medical Association*, October 28, 1899). If there are no adhesions over the bleeding lung, this method is immediately available, and the question of the patency of the pleural cavity is readily determinable by the manometer. In all of these cases its employment seems preferable to that of the more crude method of determining adhesions proposed by Murphy. Finally, it would seem, when the pericardium has to be opened, that adhesion of the two pleural layers overlying it might previously be determined by this method. If adherent, a fairly direct route to the pericardium would be open. If not adherent, a more indirect course would have to be taken to avoid pleural infection.

While the two instruments to which attention has been called have no special relation to each other, they have been presented together because they illustrate the constantly increasing debt which clinical medicine and surgery owe to physiological research.

PISTOL-SHOT WOUNDS.*

BY THOMAS HAYES CURTIN, M.D.,
NEW YORK.
CORONER'S PHYSICIAN, BOROUGH OF THE BRONX.

IT is my intention to discuss the subject of pistol-shot wounds from a purely medico-legal standpoint, and to point out briefly the manner of making examinations in these cases. The pistol and gun-shot expert has come into prominence lately in a number of criminal trials, and it may safely be said that such testimony shows less discrepancy than that of nearly all expert witnesses. As the general practitioner or the hospital surgeon is usually the first to see a shooting case, whether it be accidental, suicidal, or homicidal, and as the first observations are the most important—in fact, generally offer the only opportunity for a complete examination—it is important that a proper and thorough examination of the patient and of the surroundings should be made, and the result reduced to writing at that time. By doing this other lives may be saved and the guilty brought to justice.

Death from pistol-shot wounds is caused primarily by shock or hemorrhage, the latter being the more frequent cause. Secondarily, death results from sloughing, septicæmia, pyæmia, gangrene, erysipelas, or it may result from operative measures undertaken with the hope of saving or prolonging life.

At times the question may arise as to whether a pistol-shot wound was produced before or after death. If coagula and effusion of blood are present, it was produced before death. Neither coagula nor effusions of blood are caused by wounds on the cadaver except when a large vein is opened.

In the examination of these cases we should first look for the wound of entrance, and then for the wound of exit, if any. In some cases, and they are invariably suicidal, we find no visible external marks of any kind, except perhaps a little blood around the mouth. I refer to those cases in which the person shoots himself in the mouth, the bullet going upward through the soft palate into the cranial cavity. The size of the wound of exit is from three to four times that of the wound of entrance, and the opening is irregular, resembling a small, lacerated wound

The *distance the pistol was held* from the person when fired is usually the most important point in the criminal courts, and this can be quite accurately determined in most instances. We must examine carefully the entrance wound as to size, and the presence of powder grains, powder marks, smoke, burned hair, or skin. Generally speaking, when a pistol is held tightly against the skin the entrance wound is large as compared with the caliber of the pistol, the edges of the wound are burned and lacerated, and there is no surrounding area of blackening, burning, or powder staining. The staining is in the subcutaneous tissues, and the powder grains are found along the track of the bullet. If the clothes should intervene, they are scorched and blackened, and at times ignite. If the pistol be held from one to two inches away from the body, the entrance wound is small and the edges are ecchymosed. Surrounding the wound is an area, from one-half to two inches in diameter, in which the skin is blackened and scorched and the hair is burned to the skin. Outside of this is another zone of blackened skin, but there are no burned powder grains imbedded. The farther away the pistol is held up to a certain limit the more distinct are the imbedded powder grains, and outside of the last two zones described we usually find a few isolated powder grains. The burning of the skin and hair is regarded as the most certain diagnostic point concerning the distance of the pistol when fired. As the pistol is brought farther away there is less burning, the grains of powder are more distinct, and very little smoke is present.

Dr. Charles Phelps thus summarizes the results of his experiments: Burning of the skin is present up to a range of six inches; it is variable, however, from three to six inches. The presence of powder grains shows that the range has not exceeded five feet, while smoke stain is constant up to a distance of eight inches. If the pistol has been held at some distance, ten to twenty feet or more, the entrance wound is small and rounded, no blackening surrounds it, and there are no marks of powder, smoke, or powder grains. The diameter of the area of blackening, burning, powder grains, etc., surrounding the wound of entrance is usually the larger the farther away the pistol was held when fired, but this is unreliable as compared with the sign of burning. Of course, the caliber of the pistol, length of barrel, the kind of

*Read before the New York Celtic Medical Society, June 24, 1901

powder, and the age of same are all to be considered, and experiments should be conducted on the cadaver with the same pistol and bullets as used in the case, there being little difference in the wounds produced by pistol shot on the dead or on the live subject.

Continuing our examination of the *entrance wound*, we notice that in head cases there is very little bleeding; oozing of brain matter is present in about 50 per cent. of the cases, but both these are at times absent, and I recall a case of pistol wound of the head in which a diagnosis of apoplexy was made by the attending physician, and the wound was not discovered until three hours later, and then by another physician. One should notice the shape of the entrance wound, whether distinctly rounded, as it is when the pistol is fired directly at the person, or whether it is tunneled or grooved. This is, at times, very important in determining the relative positions of the interested parties when the shot was fired. Entrance wounds are smaller than the caliber of the bullet which has produced them, except when the pistol has been fired in direct contact. This diminution in size is due to the elasticity of the skin.

The *penetrating power* of pistol shots depends on the caliber of the pistol, the kind of bullet, the brand of powder, its age, and the character of the tissues which the bullet traverses. In my own observations of pistol-shot wounds of the head, I have rarely seen an exit wound. A 22-caliber bullet fractures the skull; it may or may not lacerate the meninges, and it but rarely enters the cranial cavity. A 32-caliber bullet penetrates the brain and, if it passes through the squamous portion of the temporal bone, it usually produces a comminuted fracture of the bone opposite. By careful external palpation the fracture can often be detected, and by a short incision the removal of the bullet and of the fragments of bone can be effected. The bullet will be found lying flat on the surface of the brain. This condition was present in four of my cases, and the bullet was removed in the manner described. From the character of the fracture it seems to me that during the passage of the bullet through the cranial cavity it twists on itself and strikes the inner table with its long side, and not by the point as one would expect. A 32-caliber bullet passing through the mastoid portion of the temporal bone penetrates and lacerates the brain, but goes no farther, and, as a rule, is found as it has fallen back into its own track. Bullets of 38 to 42-caliber penetrate, and, in some cases, perforate. Accurate anatomical description of the positions of the wounds of entrance and of exit should be made, and the direction of the wound should be accurately determined. Both these may be of service in locating exactly the position of the person who fired the shot as well as the position of the wounded man, whether he was standing, falling, or lying down when shot. Bullets are sometimes distorted or twisted into a leaden mass, so that their caliber is unrecognizable, by passing through bone.

At times it is very important in giving legal testimony that the *caliber of the bullet* be known. This is determined by accurately weighing the leaden mass and comparing the result with the standard weights of different calibers. The caliber sought for will be that one which corresponds with a weight exceeding by a few grains the weight of the leaden mass. This is because the bullet loses weight in its course. In one of my cases, in which the bullet passed through the mastoid process and into the base of the skull, this loss in weight amounted to nine grains.

Examination of the pistol.—At times a chemical analysis of the bullet may be necessary to prove it to be identical with those in the pistol of the accused. Pistols should always be examined to determine if they have been recently discharged. There is no precise rule for this determination. After a pistol has been fired the barrel is lined with a black deposit which consists of sulphide of potassium and charcoal, and this deposit when diluted with water gives a strongly alkaline reaction and has the odor of sulphuretted hydrogen. On the addition of a few drops of a solution of acetate of lead a deep brown precipitate forms. If the pistol has not been fired for hours or days, according to the degree of exposure, this black precipitate changes from the sulphide to the sulphate of potassium. The latter gives a neutral reaction in a watery solution, and a white precipitate on the addition of the acetate of lead. If the time which has elapsed amounts to weeks or months, traces of the oxide of iron as well as of the sulphate of iron will be found.

Wounds made by blank cartridges.—In conclusion, I think it opportune to direct your attention to wounds produced by blank cartridges. The relation of tetanus to wounds of this character is well known to all of you. As to whether or not the wadding is the agent which carries the germs into the system it is well to remember that it has been known to penetrate to a depth of two inches. Its removal is, of course, imperative, and is essential to the proper treatment of these wounds.

187 Alexander Avenue.

Relapses After Gallstone Operations.—H. Mohr says that the consensus of opinion is that true relapses, owing to re formation of calculi, are rare, but that many other factors may cause recurrence of the symptoms after the operation. Among these are the presence of stones overlooked at the time of operation, inflammatory colic of the gall-bladder, kinking or rough manipulation of the bladder or ducts, and adhesions. The greatest safeguard against the occurrence of these is easy operating, which is possible only when the cases are taken early, before complications have arisen and necessitated difficult and protracted procedures, followed by long-continued drainage. While most surgeons remove the gall-bladder itself only when it is the seat of serious lesions, such as ulcer, contraction, infiltration, or suspected malignant disease, the great number of pseudo-relapses after cystostomy has convinced Kehr of the advisability of performing cystectomy more and more often, and reserving the cystostomy only for acute cholecystitis.—*Volkmann's klinische Vorträge.*

On the Acute Dilatations of the Heart Met with During Childhood and Adolescence.—A. D. Blackader considers the predisposing factor to acute dilatation in early life to be the rapid development of the heart at puberty; a second factor is the anæmic and impoverished condition of the blood frequently present at this time, associated with a depressed condition of the nerve centers. Toxæmia, such as is present in almost all pyrexias, is similar in effect. Acute dilatation of the heart frequently occurs in diphtheria, influenza, typhoid fever, scarlatina, with renal complications, and rheumatic fever in children. He believes that among the directly exciting causes of dilatation in youth severe and prolonged exercise—swimming, running, various games—holds a prominent place, and thinks that the games of school children should be under competent supervision. In treating the condition, rest, with regulated diet, digitalis, and strychnine, with the nitrites in distinct accentuation of the aortic sound, are recommended.—*Montreal Medical Journal.*

High Temperature in Scarlatina and Measles, as Related to Gastrointestinal Toxins and Fermentation.—Arthur DeVoe observes that rectal injections of cool water containing sulphocarbolate of sodium reduce high

temperatures in scarlatina and measles; that the temperature declines even without movement of the bowels; that more notable reduction ensues when the enema is followed by discharge of gas or dejecta, and that in the same cases and conditions the cold bath has not acted so beneficently. He has noted the presence of carious teeth in many cases of high temperature in these diseases, tending to generate toxic influences for the lower digestive tract, and suggests the use of cooling, antiseptic washes and gargles during the periods of high fever. Cooling, antiseptic enemata tend to prevent post-scarlatinal nephritis and high post-eruptive temperatures. The author extends the use of antiseptic flushings to other diseases developing high temperatures, and in which autotoxins accumulate and are active.—*Pediatrics.*

Albuminuria Following Cold Bathing.—Giacomo Remi-Picci concludes from his observations that people react very differently to cold bathing; the less robust and the thinner the individual, the more liable is he to albuminuria. This appears rapidly, sometimes within eleven minutes after the bath, and disappears after a few hours. The habit of cold bathing does not seem to prevent the appearance of the albuminuria, which, however, is slight, rarely going beyond 0.25 gram per thousand. The albumin appears to be serum-albumin. Hyaline casts are sometimes found. Polyuria usually accompanies the albuminuria, but the relation is not constant. The elimination of total solids is increased after cold bathing, whether or not there be albuminuria. Urobilinuria is not produced. Arterial pressure is increased after cold baths or douches of short duration, but after those of longer duration it is diminished for several hours. Prolonged and very cold baths cause rapid and irregular heart action, more or less diffuse cyanosis, and sometimes dilatation of the right heart.—*Il Policlinico.*

A Case of Venous Thrombosis in the Lower Limbs of a Chlorotic Patient.—Aldo Magri reports a case in which there could be no doubt as to the diagnosis of either the chlorosis or the thrombus. The researches of Castellino, as well as those of Andral and Gavarret, have established the fact that there is some condition in the blood of chlorotic patients which favors coagulation when local conditions predispose to it and to an increase in the fibrin. The circulation being somewhat slower in the lower limbs than elsewhere, it is natural that a thrombus should form in this situation; and it is also natural that it should form in the left leg rather than in the right, since the circulation there is apt to be retarded by the fact that the left iliac vein forms an angle with the ascending vena cava, and also because the right iliac artery, in passing over the left iliac vein, probably subjects it to a slight compression.—*Giornale Internazionale delle Scienze Mediche.*

The Origin of Gastric Ulcer.—W. Gordon, after mentioning the various theories which are held in regard to the causation of gastric ulcer, gives his reasons for inclining to the belief that, contrary to the opinion commonly held, the process is an inflammatory one, and that the inflammation may at least sometimes be due to microorganisms. Acknowledging that a single specimen is not enough to found a theory on, he submits one case of typical ulcer in which abundant micrococci were found. The existing theories, he argues, are unsatisfactory, and account for very few of the cases; it is reasonable to suppose that gastric ulceration, like other ulcerations, is primarily an inflammatory process; and it is also reasonable to pass from the supposition that gastric ulcers are inflammatory to the further supposition that they may be caused by microorganisms.—*The Bristol Medico-Chirurgical Journal.*

The Effect of Air Temperature on the Temperature of the Mouth.—A. Bluhm, as the result of an extensive series of observations made on himself, finds that the mouth temperature is dependent on the temperature of the surrounding medium, low temperatures of the latter causing a low temperature in the former. The range of this drop is proportional neither to the absolute degree of external temperature nor to the difference between room and out-of-door temperature, although a slight discrepancy produces a slighter drop than a greater one. The effect of the external temperature in influencing the mouth temperature varies with the individual, but is sufficiently great to have practical bearing and during the winter months the temperatures of tuberculous patients taken out of doors in the open-air treatment should be increased several tenths of a degree centigrade.—*Zeitschrift für Tuberculose und Heilstättenwesen.*

Contribution to the Clinical Study of Erysipelas.—H. Roger, in speaking of the effect of erysipelas upon tuberculous affections, says that a distinction must be made between cutaneous and visceral tuberculosis. Of three erysipelatous patients affected with lupus, two showed no modification of the lesion, while in the third the lupus lesions of the cheek were cicatrized, that of the nose unaffected. Two patients suffering from visceral tuberculosis died of the disease, the erysipelas apparently having played no part at all. In a third case, that of a man with pulmonary tuberculosis, whose general condition was fairly good, erysipelas developed without special characteristics. Five days later, however, the patient died from hæmoptysis, and the author questions whether in that and in another similar case, the erysipelas may not have been an unfavorable influence.—*Archives Générales de Médecine.*

Constitutio Lymphatica.—George Peacocke believes that lymphatism may be the explanation of many sudden deaths in children that have heretofore not been understood. He reports four cases in which it was noted that up to the time of death the children were apparently healthy, that death was sudden, and post mortems revealed no morbid appearances other than the usual lymphoid changes present in subjects of the status lymphaticus. As it is claimed that many deaths from chloroform anæsthesia, administered by competent anæsthetists, are due to this morbid condition, it is important to recognize it during life, but as yet there are no positive data for diagnosis. The discovery of local or general hyperplasia of lymphatic structures is important evidence, and blood examination may also afford valuable data.—*The Dublin Journal of Medical Science.*

The Arterial Pressure of Consumptives.—Max John publishes a series of observations which lead him to conclude that in the earlier stages of pulmonary tuberculosis blood pressure and specific gravity are normal. Diminution in these two factors indicates marked invasion of the tuberculous process, even when this is but slightly shown by the physical signs. After it has dropped below 70 mm. of mercury, a rise in pressure rarely takes place; but, excluding cases with nephritic complications, a rise, when it does occur, always points to improvement, while further decrease means progression of the disease. In emphysema both blood pressure and specific gravity are raised.—*Zeitschrift für diätetische und physikalische Therapie.*

The Physical Basis of Melancholia.—John Turner states that certain cortical nerve cells are altered in appearance in many cases of melancholia. There are also lesions in the cells of the cord, but only in advanced cases is there degeneration of the myelin sheaths, this occurring in the crossed pyramidal tract. Experiments show that the changes can arise by agents having a destructive effect on the axons of the cells involved, or by those which do not primarily affect these axons. Melancholia is placed in the latter class. The writer considers that melancholia depends on dissolutions of the nervous system affecting the sensory section of the reflex nervous mechanism, due to deprivation of the nerve cells of their normal sensory stimulus.—*Medical Press.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, October 5, 1901.

THE ABOLITION OF THE ARMY CANTEEN.

AT the time when the exertions of well-meaning, but ill-advised, temperance enthusiasts resulted in a decree of Congress doing away with the army canteen, the prediction was made in the MEDICAL RECORD that this course would be found, after trial, to have been a grave error of judgment.

The warning has been fully borne out by the testimony offered by an overwhelming majority of army officers, medical and otherwise, in favor of the canteen, as well as by the opinions in the same direction tendered on the part of the medical profession generally.

Major Louis Seaman, Surgeon U. S. A., has done yeoman service in placing before the public the canteen question in its true aspect, stripped of all the emotional sentimentality in which it was presented by earnest temperance advocates in the first instance. Dr. Seaman's able defence of the system has been well followed up recently by several medical authorities, at the meeting of the American Public Health Association held in Buffalo in the week ending September 21.

Captain Edward L. Munson, Assistant Surgeon U. S. A., read before the meeting a paper containing voluminous statistics, culled from his work on military hygiene, which went to show the undeniable benefits that had accrued to soldiers from the establishment of the canteen. For example, to quote a few of the facts thus collected, it is stated that in the six years subsequent to the introduction of the canteen, admissions to the army hospitals for alcoholism declined 23.6 per cent.; cases of delirium tremens were less by 31 per cent.; cases of insanity by 31.7 per cent. The annual average of convictions by court martial for drunkenness was brought down from 372 to 160; the rate of desertion decreased from 9 to 4.5 per cent., and the number of soldiers depositing money increased 13 per cent.

Dr. Charles R. Greenleaf, Assistant Surgeon-General U. S. A., late Chief Surgeon of the Army in the Philippines, recorded his belief in the efficacy of the canteen in promoting the physical and moral welfare of the soldiers, and Dr. Albert L. Gihon gave similar favorable evidence.

Hard facts such as these cannot be disregarded, and while allowing to the opponents of the system the possession of the most estimable of motives, it cannot but be conceded that the opinions of army officers who have the subject at their fingers' ends, and to whom the well-being of the soldiers must be a matter of the first importance, should weigh more with Congress than the views of irresponsible and enthusiastic reformers who are deplorably ignorant of the true merits of the question. So convinced were the members of the Public Health Association present at the recent meeting at Buffalo of the cogency of the arguments advanced on behalf of the army-canteen system that with singular unanimity they passed the following resolution: "That this body deplores any action in curtailing the operation of army canteens or post exchanges as formerly existing in the United States Army, and in the interest of general and military sanitation and temperance recommends their re-establishment on their former basis."

Our country's legislators cannot fail to be impressed by the remarkable consensus of opinion in favor of the re-establishment of the army canteen prevailing among army medical officers and among all those best qualified to judge of the case in a dispassionate manner, and will doubtless act in accordance with these views.

DIET IN PULMONARY TUBERCULOSIS.

IN the sanatorium treatment of this disease as carried out at the present time—and in German sanatoriums in particular—the practice is followed of stuffing patients with food. The results claimed by physicians in Germany in charge of these institutions have been so satisfactory that it has almost become an article of belief that such is the proper procedure.

From time to time, an American or British medical man has lifted up his voice in protest against carrying this method to the extreme, but his plea has been overborne as a rule by the mass of statistics which have been hurled promptly at his head by the upholders of the system. Once more, however, a physician has had the courage of his convictions, and undeterred by previous failures has boldly stated his opinion. Dr. Noel D. Bardswell of Sheffield, England, read a paper at the British Congress on Tuberculosis recently held in London, in which he declared that overfeeding in cases of pulmonary tuberculosis was a mistake, and further fortified his position by a narration of cases experimented upon, in proof of his contention.

During the autumn of last year, Dr. Goodbody of University College, London, undertook some exhaustive researches to test the effects of ordinary and forced feeding on the metabolism of tuberculous patients. The results briefly epitomized were. (1) Patients, unless closely supervised, did not eat a sufficient amount of food. (2) Patients in special sanatorium wards did excellently in every respect, judged both from a clinical and experimental standpoint. The diet in these wards was meat seven ounces, bacon two ounces, egg one, milk three pints, butter three ounces, bread seven ounces, sugar one ounce, pudding five ounces, vegetables six ounces, daily, divided into three meals. (3) Patients after taking this diet, when given a considerably larger quantity of food, did not give such satisfactory results. They gained weight at a greater rate, but in several cases with deterioration of general health, and laboratory results indicated deranged metabolism. Coincidentally with these experimental results, indicating deranged metabolism, the patients' condition from a clinical stand

point became less satisfactory, and anorexia and dyspeptic symptoms appeared.

The contrast to the bad effects produced by excess of proteid—the inclusion of very large quantities of fat in the diet—led to practically no diminution in the percentage absorption of fat. The observers for purposes of comparison then made similar experiments upon themselves, and noted rapid gain in weight, at the expense of general health. The derangement of health after three or four weeks of forced feeding was such that the experiments had to be stopped, as the observers were unable to go on with their ordinary avocations.

The results thus obtained from experiments are now being put into practice at a Scotch sanatorium. So far the results have shown that the very large diet often given in sanatoria is to a large extent unnecessary, and often harmful.

The fact cannot be denied that a person suffering from tuberculous disease of the lungs requires a sufficiency of good nourishing food, suited to his condition. On the other hand, it is open to doubt whether the practice pursued in the majority of sanatoria of cramming patients indiscriminately with a vast quantity of food is not carried out with frequent injurious effects. It would seem that Drs. Bardswell and Goodbody are right in their assertion that each patient suffering from pulmonary tuberculosis should be experimented with until the nature and quantity of diet best calculated to benefit his particular case have been determined, rather than to overload the stomach with food irrespective of other considerations. Undoubtedly, much has yet to be learned with regard to the most efficacious dietetic treatment of consumption.

"A FULL PATHOLOGICAL REPORT TO BE FORWARDED IMMEDIATELY."

If a patient should come to a physician and request that he be completely freed from a chronic disease, say tuberculosis or syphilis, within twenty-four hours, the physician would think him either densely ignorant or seriously demented. Yet the request for a full and immediate pathological report, which so often accompanies specimens sent to laboratories for examination, is not less rational in very many instances than the demand of that unreasonable patient. Pathologists would probably not have occasion to complain of such impossible demands if the majority of physicians were aware of the fact that in any case a number of days, and in some instances weeks and months, are required to prepare a specimen before sections can be made, to say nothing of the time required for staining and examining the finished sections.

Let us take, for example, the simplest possible case: A piece of ulcerated skin is to be examined for evidences of tuberculosis or syphilis. Supposing that the pathologist has nothing to do for the nonce and that he begins work on the specimen as soon as it arrives, the tissue must be submitted to the following preparation before it is ready for examination: (1) It is cut into suitable pieces and placed in a 5-per-cent. solution of formaldehyde for twenty-four hours. (2) The formalin is washed out with water. (3) The specimen is placed in equal parts of alcohol and ether for from twelve to twenty-four hours, or longer if required for thorough hardening. (4) It is then placed in a thin solution of celloidin for a similar length of time. (5) It is transferred to thick celloidin where it remains for about twenty-four hours. (6) It is mounted upon a block of wood, glass, or vulcanite, and imbedded in celloidin, which is allowed to dry in the air. (7) The block with the tissue is placed in chloroform or 70-per-cent. alcohol for twenty-four hours, in order to harden the celloidin. (8) The tissue is now ready for cutting with the microtome, and the sections may be immediately stained, cleared in an essential oil, mounted in balsam, and examined. Thus from three to five days will have elapsed before the specimen is ready for the microscope. It may be added, however, that for cases in which an examination is urgent, there are several quick methods, such as freezing, etc., whereby sections may be cut and examined in a few hours, and also that the process described above has been, under the stress of necessity, so shortened that but two hours were allowed to each solution, so that the sections were cut and stained within twenty-four hours. With such shortened methods, however, the results obtained can never be so satisfactory as with that described in detail, for with the rapid methods the tissues cannot be properly hardened, fixed, and imbedded.

The height of absurdity is reached when requests for immediate reports accompany tissues so delicate that they take weeks to harden, or which are so infiltrated with calcium salts that decalcification is necessary—a process which usually means weeks of maceration. Similar examples are met in cases in which specimens of brain or spinal cord are received with the request to examine the lesions and to trace the degenerations through the medulla and cord. This last procedure would require, in the first place, fixing and hardening, which for small pieces of tissue may take from five to ten days (in osmic acid), and for large pieces, such as the whole cord or brain, would require months. For delicate work it is also often necessary to imbed sections of brain or cord before cutting; then follow the operations of cutting sections or serial sections, staining, and mounting. It can readily be imagined that a request for an immediate report in such a case meets with but little response on the part of the pathologist.

The Canteen.—Captain Edward L. Munson, Assistant Surgeon U. S. A., made an eloquent plea for the re-establishment of the post exchange in the army at the meeting of the American Public Health Association in Buffalo a few days ago. According to the convincing statistics collected by him and presented to the association, in the six years following the introduction of the canteen, the admissions to the army hospitals for alcoholism fell off 23.6 per cent.; delirium tremens diminished 31 per cent., insanity 31.7 per cent. The annual average of convictions by court martial for drunkenness fell from 372 to 160; the rate of desertion decreased from 9 to 4.5 per cent., and the number of soldiers depositing money with the paymasters increased 13 per cent. Captain Munson's views are shared by the members of the Board of Managers of the National Soldiers' Homes, who have been making their annual inspection of the homes at Hampton, Va.; Dayton, Ohio; Marion, Ind.; Danville, Ill.; Leavenworth, Kan., and Santa Monica, Cal. They favored the continuance of the canteen in the homes, as the veterans were less likely to drink hard liquor and were more easily governed when they could get mild alcoholic beverages with a resort to "fence jumping."

News of the Week.

Complimentary Dinner to Professor Rudolf Virchow.—It is proposed by pupils, friends, and admirers of Rudolf Virchow, to celebrate his eightieth birthday at a dinner to be held on October 12, under the chairmanship of Dr. William Osler, at a place to be announced to those who will have subscribed. The price of the dinner ticket will be $10. Replies are to be sent to the Chairman of the Committee, Dr. A. Jacobi, 19 East Forty-seventh street.

Rinderpest in South Africa.—The correspondent of the *Sun* telegraphs from Pretoria that rinderpest is virulent there. The outbreak was first noticed about September 4, and the disease has now spread through the Transvaal and the Orange River Colony. Energetic measures have been taken to inoculate all the government and private stock now in the hands of the British, and it is said that the pestilence has already been checked. The stock that is still in the hands of the Boers is expected to suffer heavily.

The Famine in Russia.—The evidences of approaching famine in many of the governments of Russia are accumulating, and the officials are beginning already to take measures to reduce to a minimum the inevitable suffering that will ensue. The sum of 96,000 rubles ($48,000) has been appropriated for the government of Saratoff; 407,000 rubles ($203,000) for Tauris, 100,000 rubles ($50,000) for the non-military peasants in the Don basin, and 190,000 rubles ($95,000), with a supply of autumn seed, for the government of Yekaterinslaff. On August 15 the central government's famine fund amounted to only 530,000 rubles ($265,000). Emperor Nicholas ordered that this be increased to 14,000,000 rubles ($7,000,000). According to the reports of the governors, State assistance is required in nineteen provinces, not counting the country of the Don Cossacks.

School Inspections in Syracuse.—The Board of Health of Syracuse, N. Y., will have a monthly health inspection of all children in attendance at the public schools this winter. The eyesight will be tested, and each child will be examined as to its physical condition, and especially as to the presence or absence of contagious diseases of the eyes and skin. Instruction will also be given by the inspectors regarding the proper method of sitting at the desk, and other points of hygiene.

The Health of Havana.—The report of Major Gonzas of the health conditions of Havana during August is again most satisfactory. The number of deaths was 480, which is a smaller number than has occurred in any August since 1889, when the records began. The least number was 559 in the year 1900; the greatest, 1,978, occurred in 1898; the average was 902. The rate per thousand for August was 22.24, which compares favorably with that of many cities of the civilized world. Not a case of smallpox has occurred since July, 1900, and this even though no quarantine is in force against New Orleans, New York, and many other places in which smallpox exists. The smallest number of deaths from yellow fever occurring in any August since 1889 was 13 in 1899; the greatest was 262 in 1896; the average is 840. This year only two deaths have occurred during the month. The yellow-fever season in Havana has usually begun in April, reaching its height in September. The least number of deaths from this disease in the five months during the period since 1889 was in 1890, when there were 18; the greatest number was 603 in 1897; the average is 226. This year during these five months only 3 deaths have occurred from yellow fever. The authorities are convinced that this freedom from Cuba's former scourge can be due only to the methods of disinfection adopted, that is, through destruction of infected mosquitos in the neighborhood of the focus of infection.

An English Coroner's Jurisdiction on an American Man-of-War.—The London *Mail* tells of a curious conflict of authority occurring not long since at Southampton, England. The warship *Chicago* had been lying off Neitley for some days, and one morning a member of her crew was found unconscious in a boat lying alongside. He was lifted on deck, and died soon afterward. The ship's surgeon made a post-mortem examination, and the cause of death was satisfactorily made out. An officer went ashore, and arranged for a funeral, with full naval honors, in Southampton Cemetery. But the registrar of deaths could not accept the certificate signed by the ship's surgeon, not only because it was not made out by a registered medical practitioner, but also because death was not the result of natural causes. The coroner was then seen, and said that as soon as the body was landed it would be his duty to hold an inquest. To this the officer of the ship demurred, pointing out that the deceased was not a British subject, and that it was not an English vessel. The coroner cited English law, and was answered with quotations from the American naval regulations. The argument was pursued in perfect good temper, but neither side would give way, and so the funeral was abandoned. The ship sailed a few hours later, and when she had steamed beyond the three-mile limit, the body was committed to the deep.

Transactions of the Thirteenth International Medical Congress.—The secretary-general of the Paris Congress announces that the volumes of transactions, both of the general sessions and of the section work, have been printed and distributed. Any member who has not received the volumes he is entitled to is requested to communicate with the publishers, Masson & Co., 120 Boulevard St. Germain, Paris, before December 31. After that date, no complaints of the non-receipt of volumes will receive attention.

Was there Hospital Mismanagement in South Africa?—Dr. A. R. Friel, who says that he was on duty as a surgeon in South Africa from March to October, 1900, writes to the *British Medical Journal* that he heard and saw much of what Mr. Burdett-Coutts described in the papers regarding the alleged unnecessary hardships to which the sick and wounded were submitted in the British Army hospitals. He says that immediately after these letters were published an immense improvement took place in the treatment of the sick by the authorities; and he adds that both the soldiers who fall sick, and those at home who have relations and friends at the war, owe Mr. Burdett-Coutts a debt of gratitude for the better treatment which the latter now experience.

Nicholas Senn Prize Medal.—The committee on the Senn Medal beg leave to call attention to the following conditions governing the competition for this medal for 1902: 1. A gold medal of suitable design is to be conferred upon the member of the American Medical Association who shall present the best essay upon some surgical subject. 2. This medal will be known as the Nicholas Senn Prize Medal. 3. The award will be made under the following conditions: (*a*) The name of the author of each competing essay shall be enclosed in a sealed envelope bearing a suitable motto or device, the

essay itself bearing the same motto or device. The title of the successful essay and the motto or device are to be read at the meeting at which the award is made, and the corresponding envelope is to be then and there opened, and the name of the successful author announced. (*b*) All successful essays become the property of the association. (*c*) The medal shall be conferred and honorable mention made of the two other essays considered worthy of this distinction, at a general meeting of the association. (*d*) The competition is to be confined to those who, at the time of entering the competition, as well as at the time of conferring the medal, shall be members of the American Medical Association. (*e*) The competition for the medal will be closed three months before the next annual meeting of the American Medical Association, and no essays will be received after March 1, 1902. Communications may be addressed to any member of the committee, consisting of the following: Dr. Herbert L. Burrell, 22 Newbury Street, Boston, Mass.; Dr. Edward Martin, 415 South Fifteenth Street, Philadelphia, Pa.; Dr. Charles H. Mayo, Rochester, Minn.

Philadelphia County Medical Society.—A lantern demonstration was given on September 26, on the occasion of the annual meeting of the Medical Society of the State of Pennsylvania. The subjects discussed were as follows: The Life History of the Ovary, by Dr. John G. Clark; Some Lesions of Diphtheria, by Dr. Richard M. Pearce; Skiagraphy in Supposed Sprains, by Dr. Geo. G. Ross and Mr. M. I. Wilbert; The Various Types of Smallpox, with Remarks upon Differential Diagnosis, by Dr. Jay F. Schamberg; Some Medical Uses of the *x*-Rays, by Dr. M. K. Kassabian; and The Kromskop, by Mr. F. E. Ives.

A Possible Source of the Gangrene in the Case of the Late President.—Dr. W. G. Garrigues of this city writes: "Bacillus emphysematosus is constantly found in the intestine, where it is not only harmless, but useful. In the vagina it becomes the cause of emphysematous vaginitis. If it enters the uterus of a puerpera, it gives rise to the dangerous tympania uteri, and sometimes the ominous septic emphysema. In general surgery it is the cause of one of the most dangerous wound diseases—acute septic gangrene. It is easy to imagine that in a body with lowered vitality, this bacillus wandered from the neighboring intestine to the tissues behind the stomach, where the gangrene was found."

The Fight Against Tuberculosis in Norway.—A sanitary league has been organized by the women of Norway to aid in the war against consumption by instructing the women of the poor. Lectures will be given and tracts will be distributed imparting information regarding the measures necessary to prevent the invasion of the home, and to limit the spread of the disease should any member of the family be already a sufferer.

Naval Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the Medical Corps of the Navy, week ending September 28, 1901: September 20—Assistant Surgeon F. A. Asserson, Assistant Surgeon J. W. Backus, ordered to the Naval Hospital, Cavité, P. I. Assistant Surgeon A. E. Peck, ordered to the *Manila*. September 24—Assistant Surgeon C. R. Burr, resignation accepted to take effect September 25. Assistant Surgeon D. G. Bebe, detached from the *Marietta*, and ordered home to wait orders, when vessel is put out of commission. Assistant Surgeon E. J. Grow, detached from the *Castine*, when put out of commission, and ordered home to wait orders. September 26—P. A. Surgeon E. M. Shipp, detached from the Naval Hospital, Cavité, and ordered to the *Celtic*. Assistant Surgeon W. L. Bell, detached from the *Celtic* and ordered to the naval hospital, Cavité, P. I. Assistant Surgeon J. W. Backus, detached from the Naval Hospital, Cavité, and ordered to the *Brooklyn*. Assistant Surgeon F. A. Asserson, detached from the Naval Hospital, Cavité, and ordered to the *General Alava*.

Bequests to Hospitals.—Under the will of the late Harriet Wilcox the New York Skin and Cancer Hospital will receive $20,000, and the Home for Consumptives, $10,000; under that of Daniel T. Hoag, St. Luke's Hospital in this city will receive $3,000; under that of Charles H. Hayden of Boston, $100,000 is left for a free bed in the Massachusetts General Hospital, and $50,000 to the Boston Children's Hospital and the Massachusetts Eye and Ear Infirmary; and under that of Susan Miln of this city, to the New York Homœopathic Medical College and Hospital $20,000 is given for four beds, and to the Children's Aid Society a house in West Twenty-third street in memory of her father, George Miln; the residue of the estate, the value of which is not stated, is to be divided among the General Memorial Hospital for the Treatment of Cancer and Allied Diseases, the Homœopathic Medical College and Hospital, the Home for Incurables, the Protestant Episcopal City Mission Society, the Society for the Relief of the Destitute Blind, and the Children's Aid Society.

The Vermont State Medical Society.—The eighty-eighth annual meeting of this society will be held at Montpelier on Thursday and Friday, October 10 and 11, under the presidency of Dr. W. D. Huntington of Rochester. The secretary is Dr. D. C. Hawley of Burlington. A general discussion on "Typhoid Fever," to be opened by Dean Richmond of Windsor will take place on Friday morning; others appointed to take part in the discussion by the presentation of set papers are J. M. Hamilton, O. W. Sherwin, J. Waite Avery, J. D. Brewster, D. L. Burnett, and J. N. Jenne. The annual banquet will take place on Thursday evening at the Pavilion Hotel.

Medical Society of the County of New York.—At the first meeting of this society for the winter of 1901–02, the following were placed in nomination to serve as officers for the ensuing year: *President*, Dr. Frank Van Fleet; *First Vice-President*, Dr. Charles N. Dowd; *Second Vice-President*, Robert Lewis, Jr.; *Treasurer*, Dr. E. W. Peet; *Secretary*, Dr. John Van Doren Young; *Assistant Secretary*, Dr. E. P. Fowler; *Censors*, Drs. George B. Fowler, H. S. Stern, Wendell C. Phillips, Robert F. Morris, and James F. M. Kernon.

The New Brunswick Medical Society.—At the twenty-first annual meeting of this society held at Moncton, July 16 and 17, the following officers were elected: *President*, S. C. Murray of Albert; *Secretary*, W. L. Ellis of St. John; *Treasurer*, G. G. Melvin of St. John; *Trustees*, Drs. R. L. Botsford, J. W. Bridges, and A. J. Thorne. It was decided to hold the next annual meeting in St. John.

Gifts to Colorado College.—Dr. D. K. Pearsons of Chicago has given $100,000 to Colorado College, one-half the amount to be applied toward the erection of a hall of science, to which another anonymous donor had already contributed $100,000.

Precaution Against the Spread of Leprosy in Hawaii.—The Hawaiian Board of Health at Honolulu has adopted a new regulation which prevents relatives and friends of lepers at Molokai from coming into personal contact with the unfortunates. A stockade has been built and visiting relatives can talk to lepers only through two fences, which are

four feet apart. The lepers at first objected to this arrangement and threatened to break down the stockade, but were finally pacified.

Phthisical Patients Removed from St. Luke's Hospital.—At a recent meeting of the trustees of St. Luke's Hospital in this city, it was decided to annul the contract between the hospital and the House of Rest for Consumptives, whereby the latter's patients were cared for at St. Luke's. It had been found that so many consumptive patients were sent to St. Luke's that other patients were excluded, and, moreover, it was felt that the hospital was not a proper place to care for so many persons affected with tuberculosis. The House of Rest has made arrangements to send its patients to the country, where they can be better cared for.

A National McKinley Hospital.—The suggestion has been made that the building and endowment of a large hospital in Washington, to be called the McKinley National Hospital, would be an eminently fitting memorial to the late President.

The Plague.—No fresh cases of bubonic plague have occurred in Naples since the presence of the disease was discovered on Wednesday of last week. Five deaths occurred among the ten or eleven persons attacked. The disease appears to have entrenched itself securely in Brazil, the government of that country having now officially declared the city of Rio de Janeiro to be infected with the bubonic plague.

Regarding Yellow Fever on the "Ethelbryhta."—This vessel reached New York on August 21, one of the crew having died the previous evening. The appearance of the body, the history of the case, and the result of the autopsy justified the Health Officer in officially declaring it to be yellow fever, although the post-mortem evidence was not entirely conclusive. Three of the crew, whose temperatures were above normal, were removed to Swinburne Island for observation. These were afterward discharged well, having had no symptoms of the disease. The vessel was disinfected and proceeded to New York, and left there on August 25, and went to Delaware Breakwater, Norfolk, and Jacksonville, arriving at the last place on September 3. The vessel remained there (Jacksonville) for about two weeks, and then sailed for Santiago, reaching that port on September 19. On arrival, it was found that three of the crew had been sick with fever, and one died; and very soon afterward eight or ten more were affected in the same way. These were at once declared by the authorities to be cases of yellow fever. It was this condition which was reported from Santiago, and which would convey the idea that the disease had been stringing along since the departure of the *Ethelbryhta* from Progreso. Those who have given this matter careful consideration are perfectly satisfied that yellow fever is not transmitted by personal contagion or through the medium of clothing, bedding, etc., and that secondary cases do not occur after five days' removal from the infected area. No one believes that the wife of the captain died of yellow fever, and her death has been satisfactorily accounted for. She was perfectly well when she left Norfolk according to the statement of the Health Officer of that place. On the following day she was taken suddenly ill and died. The reason of this has been accounted for. Vessels which loaded at the same dock with the *Ethelbryhta* in Jacksonville were found to have a number of cases of fever on board at practically the same time that the report came from Santiago regarding the *Ethelbryhta*. The health officials of Jacksonville have examined these cases and have declared them to be malarial fever, clear and well defined, and the examination of the blood has shown the plasmodia. Comment is unnecessary. It is difficult for an experienced sanitarian to believe that the cases reported there are those of yellow fever, particularly as the latter disease does not exist in Jacksonville.

Obituary Notes.—Dr. JOSEPH H. MORRISON of St. John, N. B., died at his home in that city on September 13, at the age of forty-seven years. He was graduated from the Bellevue Hospital Medical College in this city in 1878, and shortly after receiving his degree was appointed Vice-President and Professor of Natural Science at the Pennsylvania State Normal School. In 1881 he went to Manitoba, where for five years, while also practising his profession, he was also Superintendent of Education. In 1886 he went abroad to study his chosen specialties of ophthalmology, otology, and laryngology under various masters, among others Professor Politzer and the late Sir Morell Mackenzie. While in London, he submitted to an operation for caries of the sphenoidal sinus, and during the operation one of the ophthalmic arteries was wounded, the result being an aneurysm that threatened his life. For the cure of this, first one common carotid artery was ligated and then the other, and Dr. Morrison's subsequent recovery added one to the short list of survivors of this procedure. Returning to Canada in 1892, Dr. Morrison established himself in his native city, and soon built up a lucrative special practice. He was in the prime of life, one of the leaders in his chosen profession, a man of culture and refinement, of broad and liberal ideas, an accomplished linguist, an orator with a marvelous command of English, and his untimely death will long be felt in the professional, political, and social circles of the Maritime Provinces.

The Rev. JAMES BRYAN PURCELL, M.D., rector of old Trinity Church, at Sykesville, Md., died on September 24. He was born in Dublin, Ireland, October 11, 1841. He ran away to America when twelve years old, finding a home in the far West, near the Mexican border. A few years later he enlisted in the United States Army. Tiring of army life, he entered a seminary to study for the priesthood, but left the institution, drifted to Baltimore, and studied medicine. He was graduated from the University of Maryland in 1866, and became an assisting surgeon in the army, giving up the position in 1868. After resigning his commission, he studied for the ministry of the Episcopal Church, was ordained by Bishop Atkinson of North Carolina, and then settled down to the quiet life of a country clergyman.

Dr. JEREMIAH S. TREATER died at Kutztown, Pa., on September 24, at the age of sixty-nine years. He was graduated from the Medical Department of the University of Pennsylvania in 1854, and during the Civil War was Surgeon of the 73d Regiment Pennsylvania Volunteers. He was made a prisoner at Chancellorsville, escaped, joined the Army of the Cumberland, and accompanied Sherman in his march to the sea.

Dr. PERCY J. SHUTE died at his home in Jeffersonville, N. Y., on September 29, after a brief illness, at the age of twenty-five years. He was a graduate of the Medical Department of Columbia University in this city, and was for a time on the house staff at Roosevelt Hospital.

Dr. GEORGE SHIVELY died at Philadelphia on September 29 of smallpox, at the age of seventy-one years. He was graduated from Jefferson Medical College in 1851, and served in a military hospital during the Civil War.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

INTEREST IN THE PRESIDENT'S CASE—THE SMALLPOX OUTBREAK—INDIAN MEDICAL SERVICE—SOLDIERS MEDICALLY UNFIT—BRITISH ASSOCIATION FOR SCIENCE—TYPHOID AT BELFAST—DEATHS OF DRS. THUDICHUM, TRACY, HOLLAND, AND GRIFFITH.

LONDON, September 13, 1901.

THE atrocious outrage on your President has driven most other subjects from our conversation. We watch for cables, note the temperature and pulse, discuss the condition of the illustrious patient after each cablegram, and fill up our time with expressions of opinion on abdominal gunshot wounds and their surgical management. But the individual case is the most absorbing subject, and we return to it with the avidity of our non-medical neighbors. I might fill my allotted space with this subject, but you must be overwhelmed with what is said on your side, and I will only add that on this side our sentiments are all as American as those of the Americans themselves. So I turn to some less absorbing topics.

First of all, as touching us rather nearly, the smallpox epidemic which continues in London—and unfortunately a large proportion of the younger inhabitants have grown up unvaccinated—is the result of neglect and faddism combined. It now transpires that the disease has not been as limited as at first believed, but cases have occurred in various districts, each scattered case being therefore a separate focus of infection. Although the outbreak has been kept well in hand, it is by no means over yet. There are now 122 patients under treatment at the hospital ships. Yesterday the new cases were four in number, the day before five. Dr. Bond, Honorable Secretary of the Jenner Society, has appealed for more complete official statistics. He says in previous epidemics it was not known what were the results in the vaccinated and unvaccinated, until the reports of the medical officers of health appeared months after the danger had passed, when the public had lost interest in the statistics. Prompt issue of such particulars would arrest the attention of the public, and convince all of the truth in the matter.

At the meeting of the Asylums Board on Saturday a letter was read from Dr. Blyth suggesting the publication of a series of life-size lithographs to assist in the diagnosis of the disease. Wax casts, he said, would be better, but costly. Moreover, they could only be kept in a museum for those wishing to study them, whereas a book would readily sell. It may be so just now, but when the epidemic has passed the interest in the plates would fade. It is stated on some evidence that the infection was brought from Paris and spread through a laundry.

The Director General of the Indian Medical Service has replied to some of the statements made by Dr. Mullick in his communications to the British Medical Association. In reference to the charge that the professional chairs are filled more according to grade-rank than ability, he shows that it is absolutely without foundation. Seniority does not influence the choice. Such men as Fayrer, King, Cunningham, and others have been appointed when quite young. If Dr. Mullick has some plea to make for further consideration of the natives, it is rather foolish of him to talk of hundreds of men as the peers of any set of scientists. He lays himself open to the reply that if these hundreds exist they can enter the service and prove their capacity.

Lord Kitchener has sent home as "medically unfit" a considerable number of yeomanry, and he very naturally complains that hundreds of men should have been sent to Africa suffering from serious disabilities, such as defective vision or hearing, lameness, varicocele, etc. It has been stated that some cases were the result of substitutes having been employed, but surely the number of such could not be large. It is also said that examining surgeons were requested not to be too particular, but to pass as many as possible. If this were so the military surgeons would know well enough what disabilities would incapacitate a man from service, and even civil surgeons employed for this purpose would hardly pass men so obviously unfit. It really looks as if there must have been some gross carelessness. An official inquiry is to be held, and may shed some light on the matter.

The British Association for the Advancement of Science met at Glasgow on Wednesday. The President this year is Professor Arthur Rücker, Principal of the London University, and Secretary of the Royal Society. His address was a vindication of the atomic theory, which, he declared, imparted a unity to the physical seiences, otherwise unattainable. If no other conception of matter be thinkable than that it consists of distinct physical units, then the foundations of the physical theory must be well and truly laid. The atomic theory unifies so many facts that we may fairly insist that its main structure is true—that atoms are not merely helps to mathematicians, but physical realities.

In the anthropological section Professor Cunningham explained his views of the part which the brain plays in the evolution of man, and the creation of the faculty of speech. All the more intelligent animals have the power of expressing some of the simple states of mind by vocal sounds and bodily gestures. It is to such humble beginnings he would trace the origin of speech.

In the zoological section Dr. Cossar Ewart dilated on the "Experimental Study of Variation," a subject to which he has devoted years of labor. As a result of his experiments he asserted with confidence that differences in age, vigor, and health of the parents, and difference in the ripeness of the germ-cells are patent causes of variation.

Belfast is suffering from outbreaks of diphtheria and typhoid fever. On Wednesday it was officially announced that in the previous ten days ninety-eight cases of typhoid, all of a severe type, had been admitted to hospital, the total number under treatment having thus reached two hundred and ninety-four, while nineteen cases of diphtheria were admitted in two days. One nurse had died of typhoid, and several others were ailing. The number of doctors and nurses was to be increased.

Dr. Thudichum died on the 7th instant of cerebral hemorrhage, aged seventy-two. He was graduated at Giessen in 1851, after having served as a volunteer surgeon in the Schleswig-Holstein Army. At Giessen, no doubt, he imbibed the love of chemistry which he cherished all his life; for Liebig was the ruling genius of the place.

He came and settled in London in 1853, becoming lecturer on chemistry at the Grosvenor School of Medicine. Later he had the chair of pathological chemistry and directorship of the laboratory of St. Thomas's Hospital. He made a series of reports on chemical and pathological subjects for the Privy Council and Local Government Board. In 1878 he was elected a fellow of the College of Physicians. His contributions to physiological and pathological chemistry were very numerous. His treatise on the Chemistry of the Brain appeared in 1886, the same year in which his German work on clinical chemistry was published. His chemistry was very advanced, and many of his contributions demanded much knowledge on the part of the reader, and his style was too German for English taste. He took up the subject of nasal polypi as a practical one, and was quite a specialist on that and other nasal diseases.

Dr. Samuel John Tracy, who died on Tuesday, the 10th inst., aged eighty-eight, entered the profession in 1849 as a member of the College of Surgeons. He took the L.R.C.P. Edin. in 1860.

Another octogenarian, Joseph Holland, F.R.C.S., died on the 3d inst., aged also eighty-eight.

John Griffith, F.R.C.S., is an example of early death. He was only thirty-five, but had made his reputation as a skilful ophthalmologist. He was demonstrator at St. Mary's Hospital, assistant to Mr. Critchett, and on the staff of the Westminster Ophthalmic Hospital. He wrote part of the chapter on "Refraction" in Juler's work on "Ophthalmic Science and Practice." He had long been delicate, and probably he worked too hard. He kept on bravely to the last, seeming ever hopeful and cheerful, though it was plain to every one he would not live to reap the reward of his years of toil.

OUR PARIS LETTER.

(From our Special Correspondent.)

ANÆSTHESIA AND MUSIC—TUFFIER'S STATISTICS IN APPENDICITIS—PREVENTIVE INJECTIONS OF DIPHTHERIA SERUM—RUBBER GLOVES IN OPERATIONS—NEW CURE FOR BLENNORRHAGIA.

PARIS, September 13, 1901

AT a recent meeting of the Academy of Medicine, Dr. Laborde, professor of physiology, read an essay on the use of the phonograph during anæsthesia as a means of dispelling the disagreeable effects caused by dreams of a painful nature. A dental surgeon described to Dr. Laborde the method he used in giving nitrous oxide, which consists in placing a telephonic receiver, connected with a phonograph, against each ear. When the patient is being put to sleep, the phonograph is started. The dental surgeon had noticed that the greater number of his patients before he tried this had nightmare during anæsthesia, and he thought it due in great part to the fact that the noise from the street impressed them unfavorably. Since he has been employing the phonograph, his patients have no longer complained of this, but have generally

remembered only that they heard some music. Dr. Laborde cited several cases which he was able to witness, and he felt that such a method might be found advantageous in ordinary surgery.

Dr. Tuffier's statistics in the treatment of appendicitis have just been published by one of his pupils, Dr. Dubarry, and the results obtained are of some interest. Out of fifty-two cases operated upon, either at the hospital or in his private practice, during the last eighteen months, six were operated upon when there was already general peritonitis. Death took place in four cases.

There were twenty-two cases of pericecal abscess; nineteen patients were operated upon immediately and recovered, one died after the operation which had been deferred, one patient recovered without complications, and another had a fistula. There were eight observations of acute appendicitis without either peritonitis or tumefaction. The operation was performed immediately in seven cases with good results. In the eighth case the operation was deferred and the patient died. In sixteen cases the patient had recovered from his attack before being operated on. The result of the operation was good in all cases. These statistics show, the author says, that we should operate immediately upon every case of appendicitis, for fear of complications.

The importance of making preventive injections of diphtheritic serum has proved to be the subject of lengthy discussion at the Society of Pediatrics. Dr. Ausset of Lille cited a case he had seen recently in which there were two other children in the same family differently treated. One, a child eleven months old, was immunized with a dose of 5 c.c. and escaped the infection, while another, a boy eight years old, who had been sent immediately into the country, had diphtheria, which was complicated with a severe case of otitis. Dr. Netter, who is a physician in one of the children's hospitals, has collected 32,484 observations of preventive injections. Leaving out those cases in which diphtheria supervened in twenty-four hours or after thirty days, he found there were 192 cases in which diphtheria came on notwithstanding the injection. This is a proportion of 6 per cent., whereas it is 10 per cent. when preventive injections are not made. Dr. Netter said that he had made ninety injections since the 15th of April, and had had only two cases of diphtheria among these children. Out of twenty-five children who were not subjected to the injections, there were three infections, which makes a proportion of 12 per cent. Dr. Comby and Dr. Sevestre said that they considered it useful to make these injections in families where the children cannot be strictly watched after a case of diphtheria.

Dr. Longuet, who is a former house surgeon of Dr. Guénu, the great advocate in France of the use of rubber gloves in operative surgery, has recently written an article on asepsis of the hands, and in it he described the arguments used by the different surgeons who advocated or rejected the use of rubber gloves. The arguments used for or against this are of different nature. Some surgeons consider that it is impossible to carry on surgery if such rules as Dr. Guénu's and Terrier's are applied; such as that one should wait forty-eight hours after performing a septic operation before performing an aseptic one. It is generally admitted, however, in Paris now, that it is well to use rubber gloves when performing septic operations. Experiments have been carried out by Ahlfeld, Schleich, Bazy, and Delbet, tending to show that thorough sterilization of the hands could be carried out after contact with septic material.

It should be remembered, however, that the duration of a septic operation may be much longer than that of a simple experimental contact. Moreover, Nothl, Green, Kelly, and others have shown that the microbe may still remain in the deeper layers of the skin. Clinical cases show only too well the danger there is in operating after having soiled the hands with pus, even when the most minute precautions are taken. This article favored clearly the use of gloves in a certain number of operations, but not in all, and the general opinion among Paris surgeons is that, provided no septic contact has been experienced, an operation may be well carried out without them.

A new treatment for blefnorrhagia has just been advocated, the use of picric acid. Dr. de Brun, who is professor at the French school of medicine at Bayreuth, recommends a 1 or 0.5 per cent solution; the latter preferably. The injection should be made with a small glass syringe, and left in contact with the mucous membrane for two or three minutes. A complete cure is generally obtained in from four to five days. In chronic cases, Dr. de Brun has obtained results where everything else had failed. One of the first effects of the injection is to modify the nature of the flow, which becomes almost transparent. In posterior urethritis, instillations would undoubtedly be found necessary.

Progress of Medical Science.

Boston Medical and Surgical Journal, September 26, 1901.

Spermin Crystals in Pus.—Edward T. Williams says that he has discovered a body in pus which he thinks is spermin. If his observation is not at fault, he says, this makes the fourth or fifth of the nuclein bases thus far observed in pus: adenin, guanin, or both, by Naunyn; sarcin by Kossel; spermin and xanthin by himself.

Observations on Heart Disease.—Robert T. Edes defines disease of the heart as follows: "When the heart is able readily to adjust itself to widely varying demands without distress, it is functionally healthy. When it cannot furnish all the blood that is called for without suffering, or at any rate without continuing to suffer after the strain is over, or when, after the strain has ceased to exist, it fails to return to its former condition, it is not healthy, whether we suppose that any structural change would be discoverable or not." The observation of the pulse, of the venous circulation, of localized congestion and œdema, is the real guide, he says, as to how efficiently the heart is acting. If the work is not done thoroughly, easily, and without disturbance, or if a little extra call for exertion shows that the margin of adjustability is a very narrow one, it is then the part of the physical examination to distribute the difficulty properly between the two factors—propelling force and resistance. He thinks it is a mistake to attach the greatest importance to valvular disease—a natural error, since it is that which furnishes the most definite and clearly marked signs. He raises the question whether it is possible to diagnose actual degeneration of the cardiac muscle, and answers that it is not possible always to do so with absolute certainty, yet frequently a diagnosis can be made with a degree of probability entirely sufficient for practical purposes. He thinks it doubtful whether a muscle, degeneration of which has proceeded so far that it can be detected under the microscope, could retain its full efficiency under strain, and so could escape the observation of the careful diagnostician.

New York Medical Journal, September 28, 1901.

The Abstraction of Calcium Salts from the Mother by the Fœtus a Cause of Osteomalacia.—Jennie G. Drennan advances the theory suggested by the title of her paper stating that osteomalacia is a disease, the result of a poverty of calcium salts in the blood of the mother, by which her osseous tissues are starved by the fœtus assimilating all the available salts. If her diet had been rich in salts, there would have been a sufficiency for both. The women in whom this disease occurs oftenest are those whose diet is poor in lime. The disease is commonest among the poor peasant classes in Europe, foreigners in America, and the slum classes of British cities. Naturally, in each succeeding pregnancy the supply of calcium in the tissues will be less, as in all probability the osseous tissues will not recover their first state.

Two Cases of Intestinal Obstruction Diagnosed by the x-Rays.—These interesting cases are reported by J. Rudis-Jicinski. Case 1 was that of a boy who had swallowed a tin whistle. The usual symptoms of obstruction followed. By *x*-ray examination the body was located at the junction of the small and the large intestines. Under hypodermic injections of atropine it was passed on the third day. Recovery was uneventful. Case 2 was that of a boy of twelve with usual symptoms of obstruction. A diagnosis was made of invagination of the lower part of the ileum. The *x*-rays showed the actual obstruction to be in the small gut under the umbilicus, nearly at the median line and a little to the left. Laparotomy was done, and the obstructing body proved to be a small wooden whistle. The author has made certain experiments showing that a harmless body may be swallowed and its passage through the bowels traced by the Rontgen rays. He gives the following directions for the preparation of such a body. Take a gelatine capsule No. 8, put a No. 4 shot into the same, close the capsule and cover the whole surface with a smooth layer of dental gutta-percha, which must be applied warm. In this way is made a pill, which may be easily swallowed. The gastric juice cannot act upon it, and the heat of the body will not destroy it. The shot being opaque to the *x*-rays will show plainly, and may give the direction in which the strangulation took place. Such a diagnosis is correct and may solve the problem of immediate operation.

Social Aspects of Dermatology.—In the Third Lane Lecture, Malcolm Morris treats of ringworm, favus, tinea versicolor, and erythrasma. With reference to ringworm,

his personal researches have led him to believe that there are two distinct fungi which may cause the disease, distinguishable by the relative size of their spores. In the smaller variety, the spores are irregularly scattered about like the stones in a mosaic, and interwoven with them is a felting of branching mycelium, the whole forming a sheath around the hair. The parasite eats its way into the hair and grows down toward the root; the hair becomes brittle and after a time breaks off, leaving a short stump. The microsporon attacks the scalp chiefly, in children almost exclusively. The disease produced by this fungus is often very refractory to treatment and indefinite in duration. The large-spored fungus first attacks the root of the hair and grows upward. The spores are arranged in regular chains intermingled with short, regularly jointed mycelium; they lie around the hair, sometimes inside it, sometimes both inside and outside. The ringworm caused by this fungus yields more readily to treatment than that produced by the microsporon. Morris believes that special schools should be established for children with ringworm. Favus is a more serious condition, and is sometimes associated with tuberculosis, and cases of death have been reported from gastrointestinal irritation caused by the presence of the characteristic lesions in the stomach and intestines. Legislation is needed for its repression, and emigration from those countries where the disease is rife should be most rigorously supervised.

Medical News, September 28, 1901.

Intratracheal Injections in Bronchial and Pulmonary Affections.—Willis S. Anderson believes that the method of intratracheal injection is of no advantage in acute bronchitis, at least during the congestive stage. It is of distinct advantage in subacute and chronic bronchitis. It is of positive benefit in bronchiectasis. It is valuable in pulmonary tuberculosis, relieving many of the symptoms, especially those due to secondary infection. It quickly relieves the distressing symptoms of asthma. The amount of relief and the permanency depend largely upon the predisposing and exciting causes. It in no way interferes with other lines of treatment. The writer has never seen harm follow its use, although in a very few instances it excited severe coughing for a short time.

American Medicine, September 28, 1901.

The Hygienic and Mechanical Treatment of Heart Disease.—Boardman Reed states that cardiac disease is often due to autointoxication, especially to poisoning by the alloxuric bases. Cure or amelioration in such cases requires at first, in addition to an appropriate diet, not too nitrogenous, the utmost practicable rest of the crippled organ. This cardiac rest may be further promoted by very gentle exercises which dilate the capillaries without taxing the heart. The Nauheim method of treatment spares the heart by dilating the too contracted arterioles in two ways, namely, (*a*) by stimulating the peripheral circulation through carbonated saline baths; and (*b*) by massage and forms of exercise so mild as not to quicken the pulse.

The Place of Symphysiotomy as Contrasted with Cæsarian Section.—Charles Jewett concludes that symphysiotomy is still a useful operation within a limited range of pelvic contraction. It is suited to conditions in which only very little additional space is required for delivery. It is a valuable resource, therefore, in cases in which forceps unexpectedly prove inadequate. Axis traction forceps, with the aid of posture, should always be tried before resorting to symphysiotomy. Its results would be much improved by restricting it to pelves with a conjugate of not less than 7.5 cm. in simple flattening, or 9 cm. in general contraction. Under equally favorable conditions, its total mortality should be no greater than that of cæsarian section. When the pelvic space permits, it should replace the cæsarian operation in the presence of exhaustion. It may be elected, primarily, as an alternative of cæsarian section, when the operator can be assured that the degree of obstruction is well within its safe limit. Here, the choice of operation is a matter of individual preference. Within its proper field, symphysiotomy is better than cæsarian section for an operator of little experience in abdominal surgery.

Journal of the American Medical Association, Sept. 28, 1901.

Prevention of Tuberculosis in Babes Born of Tuberculous Parents.—Clifton Scott says that the old stereotyped method of visiting the mother a few weeks before confinement, securing a specimen of her urine, and testing it for albumin is not a sufficient precaution for the safety of the child. These preliminary examinations, made at safe intervals during the last two months of pregnancy, should include a general physical examination and careful search for tubercle bacilli. Many cases will thus be found, and our knowledge of the existence of tuberculosis, in otherwise unsuspected cases, will not only enable us to guard better the mother's condition, but will save many babes from infection, through guarding against the use of the mother's milk and infection by contact. If this method be carried out rigidly, and the people are educated to appreciate its importance and value, many children of tuberculous parents can be saved from infection.

Gonorrhœa in Boys.—A. L. Wolbarst gives a general description of the disease as occurring in young boys. The period of incubation and general features are in the main the same as in older patients, but the pain is often out of all proportion to the clinical picture presented. The duration is the same as with adults, but the prognosis is better than with adults. There does not seem to be the tendency of the disease to continue in the chronic form, and strictures are not so liable to result. Barst has never seen rheumatism develop in these cases. Treatment consists in the maintenance of surgical cleanliness by means of boric acid or even weak bichloride solutions. In anterior urethritis, one-half per cent. solution of protargol may be injected three times daily, being retained for about five minutes. In posterior cases, the urethra may be irrigated with a solution of permanganate of potassium (1-6,000), or with the Thiersch solution. For internal administration, the pure oil of wintergreen, in doses of 5 to 10 minims, in milk or water, three times daily, will be found valuable in some cases. In others, an alkaline mixture, containing potassium bicarbonate and tincture of hyoscyamus, will bring relief from the pain and tenesmus.

Congenital Cystic Kidney.—A case of this nature is reported by W. Jepson, whose patient was a child successfully operated on when four months and fourteen days old. Three theories have been assigned for the occurrence of this condition: (1) retention, (2) cystadenomatous, and (3) teratological. The points of interest in the case were the following. 1. It involved only one kidney, and it developed to a very marked degree without leading to serious disturbances until these were occasioned by its encroachment upon the gastrointestinal tract through pressure. 2. The difficulties in the way of arriving at anything but a problematic diagnosis prior to direct inspection of the growth are quite insurmountable; and even inspection of the growth does not lead to a positive diagnosis until all structures from which a more or less similar condition might arise are examined as to their normality, and a diagnosis thus arrived at by exclusion. An organ thus distended no longer possesses any recognizable characteristics of its former self. 3. The case is further illustrative of the capability of children to endure what may be considered capital operations, provided that precautions are exercised in reducing to a minimum the period of anæsthesia and operation, as well as the loss of blood.

Philadelphia Medical Journal, September 28, 1901.

Thrombosis of the Cavernous Sinus; Double Panophthalmitis of Septic Origin.—Edward Jackson states that it is rare in rapidly fatal disease for the ocular symptoms to predominate. He reports two cases of this character. The first patient was a man of twenty-six years, afflicted with pulmonary tuberculosis. The affection of the eyes at first looked like purulent conjunctivitis. The swelling was marked, but the discharge was rather moderate in amount. Later, the orbital tissue became swollen. Post-mortem examination showed a clot extending into the cavernous sinus from the orbital vein, but presenting no prolongations into other cerebral tissues. It probably originated in some orbital vein. The second patient was a woman aged forty-five years, who was admitted to the hospital suffering from purulent retinitis or choroiditis involving both eyes. It was undoubtedly the result of grave septicæmia. Post-mortem examination first revealed the presence of septic pneumonia. The only point of origin that could be discovered for this septicæmia was in the left knee joint, which was filled with pus.

Laceration of the Cervix Uteri.—Henry D. Beyea enumerates the following factors upon which depends the success of treating lacerations of the cervix uteri: 1. Proper selection of cases; 2. Preparation for operation; 3. Attention to certain essential operative details; 4. Selection of the proper operation in the individual case. The chief contraindication to operation is the existence of pelvic inflammatory trouble outside of the uterus—disease of the tubes and ovaries. As a general rule, other lesions coexist with laceration of the cervix, and these also need treatment, in order to effect a cure. In many cases, considerable local treatment should be given prior to operation. In the operation, great care should be taken

to remove all of the cicatricial tissue, including that at the angles of the tear. All Nabothian cysts should be entirely removed from the region of operation. Too much tissue should not be removed from the vaginal part of the cervix. Care should be taken to place the sutures accurately and evenly. On removing the sutures, loops must not be left in the tissue. An early diagnosis should be made between bad laceration of the cervix with sclerosis and eversion of the mucosa, and beginning carcinoma of the cervix.

The Lancet, September 21, 1901.

Six Cases of Excision of the Larynx.—The histories are given by F. G. Harvey, who describes his favorite mode of operating. Of the six cases, five were in men and one in a woman. Two of the patients were living one year after operation, one died within a week after operation, and three within a year, the cause of death in one of the latter, however, being acute pneumonia.

Three Points in Midwifery.—These are mentioned by G. W. Ord. In one case of delayed after-coming head, he passed a male silver catheter into the child's mouth, and later a second one. The child cried down the catheter, the chest became inflated, and respiration was maintained in this way until the head was extracted. Secondly, the author advises the expression of the child after the birth of the head, stating that this procedure will obviate hour-glass contraction. Thirdly, he believes that scoliosis is possibly caused by traction on the child's body during birth, and that we should realize the possible injury that may be done to the spine by pulling in the various directions advised in text books.

Congenital Spontaneous Gangrene.—C. E. Richmond reports a case of this kind in a girl who showed when born two patches of dusky inflammatory redness, one just below the occiput, the other over and around the seventh cervical vertebra. These areas gradually increased in size and took on a distinctly gangrenous condition, and scattered, similar areas appeared on the scalp. The general state was one of dulness tending toward stupor. Internal strabismus supervened, suggesting the query whether it was an indication of central cerebral mischief, of which the gangrene was a "trophic" evidence, or whether it was pseudoptomain infection of nerve-centers due to septic absorption from sloughs. The child died on the fifth day. There was no evidence of syphilis.

Chronic Invalidism in Women, Its Causes and Cure.—W. S. Playfair discusses the condition known as "neurasthenia." It is essentially a disease of the middle and upper classes, and the main problem is to determine how we shall prevent its occurrence in young women. Our supervision must begin at the age of puberty and in the school room, for much of the trouble results from neglect of menstrual disturbances which, in turn, are induced by over-application to study. Out-door life and sports are by all means to be encouraged. Most of these patients suffer from defective nutrition and, what we may term in a general way, "worry." When the condition is once developed, the rest-cure should be prescribed. A nurse should be secured who possesses a combination of sympathy, intelligence, and firmness. As a rule, the patient should be removed from home surroundings. She should have systematic massage, shampooing, etc., her muscles being exercised for her in this way for at least two hours twice daily. Such a régime enables the patient to consume food in abundance, so as to build up wasted tissues and restore bodily strength. All visits from relatives, and even letters, should at first be cut off. The patient keeps to the bed for six weeks, and is then allowed to go about and gradually resume her ordinary method of living. Later, a sea-voyage is often attended with most favorable results. After ordinary tests of this kind, the patient, if she stands them all well, is to be allowed to return to her home and friends.

British Medical Journal, September 21, 1901.

A Case of Acute Puerperal Sepsis Treated with Antistreptococcus Serum; Recovery.—M. F. Hession attributes the recovery of a case of puerperal sepsis to the injection of antistreptococcus serum. The amount of serum was 10 cm., and the number of injections was three. The patient slowly but steadily improved, and the injections were not followed by any unpleasant symptoms.

A Case of Puerperal Eclampsia (Albuminuric) Treated by Morphine.—A. G. C. Irvine administered in all ⅔ grain morphine (three doses) to a patient suffering from puerperal eclampsia. Perfect quiet, a dark room, and strict milk diet were ordered. The next day, after the last convulsion, compound jalap powder gr. xl was given in the morning, and a simple [illegible] at night. The writer thinks the morphine treatment is of great value in this affection.

The Value of Neisser's Stain in the Diagnosis of Diphtheria.—R. M. Beaton, J. Foord Caiger, and Walter C. C. Pakes believe that by Neisser's stain a positive diagnosis is made more certain for those who are not experts, since it is often easier to diagnose the Klebs-Loeffler bacillus after staining by Neisser than after staining by ordinary methylene blue. A trustworthy positive result may be obtained from the microscopical examination of a preparation made direct from the swab, and this method with Neisser's stain is more reliable and more obvious. The use of Neisser's stain does not appear to introduce any fallacy not found in the application of other methods.

Case of Primary Chancre of the Tonsil; Probable Infection from a Tonsillotome.—Peter H. Abercrombie reports this case. The patient, aged twenty-eight years, had his tonsils removed. One of the instruments used was not sterilized. About a month after the operation, the throat became sore. The diagnosis was made of primary chancre. The following treatment was prescribed: (1) Liquor hydrargyri perchloridi 3j., potassii iodidi gr. d. s.; (2) a mouth-wash of lotio nigra, half strength; (3) lozenges each containing ½ gr. of grey powder; (4) a pigment of iodine and carbolic acid, of each gr. iv. to 3j. Alcohol and tobacco were forbidden. He has continued well ever since, though still under treatment.

Two Successful Cases of Operation for Perforated Gastric Ulcer.—E. Collingwood Andrews reports these cases. The first patient was a woman, aged twenty-three years. The perforated ulcer was found near the cardiac orifice on the lesser curvature. The peritoneum round the perforation was united by two layers of Lembert sutures. The surrounding area was carefully sponged, and the whole peritoneal cavity flushed with saline solution. A gauze drain was inserted into the upper part of the wound, and a large drainage tube in the lower angle. The patient made a good recovery. The second patient was a man of thirty years. The perforation was three-quarters of an inch from the pyloric orifice on the lower border. A single row of Lembert sutures was first inserted with silk, and then over these another series of Halsted sutures. The area was well sponged, and a large rubber drainage tube inserted. The patient recovered.

Note on a Simple and Rapid Method of Producing Romanowsky Staining in Malarial and Other Blood Films.—W. B. Leishman, after describing the process of making the dye which constitutes, or at least contains, the active staining ingredient in Romanowsky's method, speaks of its best solvent. This he has found to be pure methyl alcohol. The dye is dissolved in this alcohol in the proportion of 0.15 per cent., the resulting solution being kept in stoppered bottles until used. Films of blood or smear preparations are made in the usual way and dried in the air. The coverglass, with the film uppermost, is seized by forceps, while three or four drops of the stain are put on the film. The forceps is gently rotated from side to side in order to distribute the fluid. After thirty seconds, six or eight drops of distilled water are added and the rotation continued. The film now stains for five minutes, when the stain is gently washed off with distilled water, and a few drops of water are allowed to remain on the film for one minute. The specimen is now ready for examination, either directly in water under a ⅓ or ½ objective, or, after drying (without heat) and mounting in xylol balsam, under an oil-immersion lens. The entire process from the withdrawal of the blood takes only seven or eight minutes.

Munchener medicinische Wochenschrift, Sept. 3 and 10, 1901.

The Treatment of Traumatic Tetanus.—A. Dehler's patient was a middle-aged woman who wounded the dorsum of the left foot with a pitchfork. Twelve days later tetanic symptoms began to appear, and when the patient came under observation on the fourteenth day well-marked trismus and risus sardonicus were present. After the removal of a piece of straw from the already healed wound, its edges were excised and the cavity was cauterized with trichloracetic acid. Tizzoni's antitoxin and chloral were given, the former at first in large doses and then in diminishing amounts as the severity of the symptoms decreased, and recovery was complete on the nineteenth day after the beginning of treatment, during which time 10 gm. of antitoxin were used in thirteen doses.

The Surgical Treatment of Strictures of the Lacrymal Duct.—Passow describes an operation which he admits is difficult, but still adapted for use in certain obstinate cases. At the first session, the anterior extremity of the inferior turbinated bone is removed by means of Cooper's scissors. After the reaction from this procedure has

subsided under general anæsthesia, enough of the turbinated crest of the upper maxilla and lacrymal bone is removed by chiseling to liberate the duct up to the lacrymal sac. A Bowman's probe in the duct serves as a guide, and when its free movement shows that the membranous canal has been fully exposed, the latter is slit up its entire length with a fine probe-pointed knife. The author performed the operation four times on three patients with excellent functional results. The method is not intended for use except in cases that have resisted other forms of treatment, when it is preferable to the alternative measure of excision of the lacrymal sac on account of the absence of subsequent cicatricial deformity.

The Cardiac Condition of Caisson Workers.—Hornung examined the hearts of a number of caisson workers immediately before and immediately after entering the chambers, and again at the end of the day's work, just before and after the reduction in pressure. The results showed that the rise in pressure was in all cases followed by an increase in the heart's height and breadth, the latter change being more marked on the right than on the left side. The pulse changes were less consistent, but the general tendency was for a rise in rate to take place. At the end of the period of work, the size of the heart had usually diminished somewhat.

Membranous Dysmenorrhœa.—Kollmann says that further observation of the case on which it was founded leads him to withdraw his conclusion that this condition can undergo spontaneous cure. No connection exists between this affection and either pregnancy or abortion, neither does it entail sterility. The membranes are not the result of inflammation of the uterine mucosa, but care is necessary to distinguish them from the products of croupous inflammation or blood clots. The pain experienced is not the result of the separation or expulsion of the membrane, which is not a mechanical process due to excessive blood exudation. The membrane does not possess a definite anatomical structure, and may vary at different times in one and the same patient. The disease is much commoner than is usually thought, and is often overlooked by the practitioner.

Surprises in Herniotomies.—E. Meusel describes two cases deserving the title given. In one, the rupture of a man of seventy-two years became first irreducible and five days later incarcerated. On opening the sac, after reposition of most of the gut, a loop was found compressed by a large tumor of the mesentery which subsequent examination showed to be carcinomatous. The affected portions were resected, and the operation was concluded in the usual way with good result. The other patient was a boy of four years whose hernia was of one year's standing. On incision, the sac was found occupied by a mass of intestines matted together and covered with tubercles. It was impossible to disentangle the convolutions of gut, and discouraged by the presence of the general tuberculous peritonitis the operator desisted from further attempts. A fecal fistula developed, however, and several weeks later the closure of this was undertaken. On exposure of the contents of the sac, to every one's surprise all trace of disease was found to have disappeared, so that after resecting the adherent bundle of intestine an end-to-end anastomosis was done, and the wound was closed. Perfect recovery followed and it is intended to perfect the closure of the hernial portal by a secondary operation.

Experimental Observations on the Tuberculous Infections of Childhood.—Dieudonné repeats the observations of Feer, Cornet, and others, who say that the ages of predisposition to tuberculosis during childhood vary greatly. Up to the sixth month, the disease is very rarely observed, but from this time on, the frequency increases rapidly, and reaches a maximum at the end of the first or second year, only to fall again in the third year. These facts are explained by the mode of life of children, which changes very considerably during these periods. In early infancy the child is kept mainly in bed or in its nurse's arms, but later on it spends much of its time on the floor, creeping about, and therefore is exposed to infection through the inhalation of dust, and its direct conveyance through the medium of dirty hands from floor to mouth and nose. In order to test the possibility of such transmission of tubercle bacilli, the author made cultures from the hands and noses of fifteen children, one or both of whose parents were tuberculous. In two instances the organism was found. A simple prophylactic measure that readily suggests itself is always to place a clean sheet on the floor before the child is set down to play.

Blood Cysts.—A. Gebhart describes a case of multiple blood cysts occurring in the intercostal musculature of a man of good previous history, and going on to erosion of the ribs. When the man came under observation, a large, fluctuating, elastic tumor was found occupying the left infra-axillary region, and yielding dark fluid blood on aspiration. A diagnosis of new growth, probably sarcomatous, of the rib was made, and an exploratory incision was done before an attempt was made to remove the tumor. On cutting into the mass, it was found full of dark uncoagulated blood, and further examination revealed the fact that the adjoining rib had been largely eroded, and its irregular ends were projecting into the cavity. These portions were trimmed with bone forceps, and the hollow was packed with iodoform gauze. It promptly closed down and granulated, though occasional hemorrhages from the wound took place, but after some weeks a similar swelling appeared just below the site of the old one. This was found to be of the same nature, and was treated in a similar way; for a time the patient did well, in spite of the severe hemorrhages; but finally, several months later, he succumbed to chronic sepsis. The author calls the condition multiple hæmatoma, but does not attempt to explain its underlying cause.

Section of the Median Nerve; Recovery.—M. O. Wyss reports a case of accidental section of the median nerve with subsequent complete regeneration which, as it occurred in the person of a physician, could be very carefully studied both subjectively and objectively. The conclusions to be drawn from the very detailed account of the case are that sharp severance of a nerve does not cause immediate pain, nor does such develop until after the second day, when it appears in the anæsthetic areas, and is a sharp and lancinating neuralgia. Pain during regeneration is always most severe in those regions in which the points of the advancing axis cylinders are situated, which spots are especially sensitive to pressure and tickling. The regions that are recovering sensibility are at first characterized by the fact that the contact of cold, and to a less degree of warm, objects is painful, *i. e.* there is hyperæsthesia to slight differences of temperature. Proximal axis cylinders can, and no doubt often do, grow out into other distal axis cylinders if the cut sections of the two stumps are not accurately superposed. Regeneration takes place also in those regions not previously anæsthetic, as shown in this case by the presence of hyperæsthesia in regions supplied by the ulnar nerve. In such cases, true trophic lesions require careful differentiation from those that are merely the result of diminished cutaneous sensibility. The severed axis cylinders regenerate at the rate of about two millimeters a day.

Berliner klinische Wochenschrift, September 9, 1901.

The Question of the Formation of Sugar from Fat in Severe Cases of Diabetes Mellitus.—L. Mohr conducted a series of uranalyses in the cases of two patients exhibiting high grades of glycosuria which persisted in spite of strict diet. The amount of aceton, present in the urine, as well as the disproportionately large amounts of sugar, led the author to conclude that the clinical and experimental work of Rumpf, Rosenquist, v. Noorden, v. Bunge, and others has established the fact that sugar-formation from fat is possible.

Bismuth Poisoning.—Droesmann quotes the observations of numerous authors who have found that the subnitrate of bismuth is capable of producing toxic symptoms after either internal or local use. In the milder cases a stomatitis resembling that due to lead poisoning is produced, with soreness of the gums, black line at the base of the teeth, and discoloration of the tongue and mucous membrane; while in severe cases intestinal inflammation and nephritis are caused. The author's own patient received a severe burn of the whole leg, which was dressed twice daily with 10-per-cent. bismuth-subnitrate ointment. Three weeks later a black sediment appeared in the urine, and three weeks later still stomatitis and dysphagia developed. No impurity was present in the preparation employed, and after discontinuing the use of the ointment prompt recovery followed.

Traumatic Necrosis of the Pancreas.—F. Selberg says that gangrene following pancreatic trauma may be explained in two ways: either the pancreatic secretion escaping from the site of rupture produces necrosis through its action on the tissues of the organ itself and the abdominal fat—a view that is supported by the fact that the lesion is usually most pronounced in the immediate vicinity of the injury; or the damaged tissues themselves may become directly necrotic and then secondarily furnish opportunity for the growth and development of bacteria. In a case observed by the author the patient, a middle-aged man, received a kick in the abdomen from a horse which rendered him immediately unconscious, and was followed in the course of the next few days by symptoms of peritonitis and left-sided pleurisy. At the time of admission to the hospital, the condition was so

far advanced that operative treatment was out of the question, and death took place a day or two later. On autopsy, there were found numerous areas of fat necrosis through the omentum, the head of the pancreas was necrotic and friable, while the rest of the organ was infiltrated with hemorrhagic exudate and discolored.

Deutsche medicinische Wochenschrift, September 12, 1901.

The Proportions of the Excreted Sodium and Potassium Salts in the Cachexia of Carcinoma and Phthisis.—R. Meyer says that normally the potassium salts excreted equal about 0.3 gm and the sodium salts about 6 to 7.5 gm., while in severe cachectic states this proportion is almost exactly reversed.

A Case of Late Apoplexy Following Trauma.—O. Bruns reports a case which is interesting from the length of time that elapsed between the reception of an injury and the first symptoms of its results. The patient was a man of forty-one years, who, while at work, received a blow on the head which was not severe enough to make him unconscious or give any symptoms beyond slight discomfort. Four days later, early in the morning, he had a severe sneezing fit, after which vertigo, vomiting, and coma developed in rapid succession. Death followed the next day, and on autopsy a severe cerebral hemorrhage, originating in a small aneurysm near the corpus striatum, was found. Only five similar cases have previously been reported. The theory of the late occurrence in these cases is that the original trauma produces enough local softening to deprive the vessels of their support, and following this aneurysmal dilatation takes place which any slight external cause, such as in this case was afforded by the sneezing, may rupture and so produce a hemorrhage.

The Operative Treatment of Punctured Wounds of the Heart.—I. Watten describes a case which makes the thirteenth reported in which the heart has been sutured, and the sixth in which the treatment has been followed by recovery. The patient was a man of twenty-three years, who came under observation two and a half hours after having received a stab wound penetrating the thoracic wall in the fourth right interspace close to the sternum. On removal of the temporary dressing, there was considerable external and internal hemorrhage, and on introducing the forefinger it was found that the pericardium and right ventricle had been wounded. In spite of possible difficulties, it was determined to attempt the suture of the heart from the right side without resection of the sternum, though to gain room it was necessary to elevate a triangular flap by cutting through the cartilages of the fourth, third, and second ribs close to the sternum. The pericardial wound was now in plain sight, and could easily be lengthened, and its edges could be drawn up into the wound. This brought into view the cardiac wound, an incision an inch long and relaxing and contracting with each heart beat. The commotion of the injured organ was so great that it was impossible to place any sutures until it had been gently pressed upward against the sternum by two fingers of the left hand. Three silk sutures were then introduced, and gauze drainage strips were left leading into the pericardium. Five weeks after the operation the patient was discharged cured and immediately resumed his trade of weaving, and two weeks later on examination was found to have a regular pulse of eighty to the minute with complete euphoria, and the ability to perform the hardest manual labor.

French Journals.

Congenital Macrodactylia.—Boinet concludes that congenital macrodactylia does not pertain exclusively to teratology. It is rarely hereditary. It is almost twice as frequent in man as in woman; it is noted more often on the right side than on the left; the finger most apt to be attacked is the middle one, next in order come the index, the thumb, the ring-finger, and the little finger. Two fingers are oftener attacked than one. The size of the affected fingers varies. Often no other anomaly is noticed. The pathogeny is still not clearly understood, though there have been many theories advanced.—*La Presse Médicale*, September 4, 1901.

Affections of the Nasal Fossæ.—Aristide Malherbe notes, among other troubles of the nasal fossæ, epistaxis. It is a symptom common to many affections of the nose and one that also takes place in a great number of maladies. Epistaxis is traumatic or spontaneous. The treatment of traumatic epistaxis varies with the cause. In simple cases, such as erosions, hot nasal injections and direct compression are excellent means of arresting the flow of blood. Spontaneous epistaxis must be treated according to the case. Light attacks generally cease of themselves. The pressure of a finger is often sufficient. Severe cases are well treated by cauterization or direct tamponade.—*Le Bulletin Médical*, September 7, 1901.

Principal Complications of Vulvovaginitis in Little Girls.—According to A. Guillaumont, the old idea that vulvovaginitis of little girls is an affection relatively benign, occasioning only local troubles, cannot be accepted now. Among the complications from contiguity are rectitis, urethritis, bartholinitis, etc. Vulvar hemorrhages are generally superficial. In the child as in the adult, blennorrhagic infection ascends and attacks the uterus, the tubes, the ovaries, and the peritoneum. Complications from inoculation at a distance embrace only the ophthalmias. The chief complication due to general infection is blennorrhagic rheumatism due to the presence of the gonococcus in the articulation. Endocarditis and pleurisy, in the child as in the adult, may appear in the course of a general gonococcic infection. The prognosis of the complications of vulvovaginitis is very generally good.—*Gazette des Hôpitaux Civils et Militaires*, September 3, 1901.

Primitive Cancer of the Liver in a Patient with Cirrhosis.—Vaulair presents this case. The patient was a man fifty-one years old. At the autopsy it was not possible to find a trace of cancer in any other organ. The man had an alcoholic history, but there was no malignant taint in his family as far as could be discovered. The first symptom was pain in the region of the liver, after which his appetite failed. The limbs began to swell and he lost flesh. Palpation revealed an enormous liver. The skin became jaundiced. He developed a peculiar repugnance to meat, and asked for soups. At autopsy, the liver was discovered to be enormous, the right lobe being entirely involved by the neoplastic growth, while the other parts appeared cirrhotic. On section, the anterior part of the right lobe was red. Here and there were islands of parenchyma, grayish in color and sclerotic. The sclerosis was of long standing and general. The cells of the hepatic lobules had disappeared through progressive autopsy and necrosis, and had been replaced by an abundant epithelial proliferation, having for a starting-point the biliary canaliculi, and presenting the characters of a glandular carcinoma.—*Journal des Sciences Médicales de Lille*, September 7, 1901.

Influence of Certain Alimentary Principles on the Quantity and Quality of the Gastric Juice.—M. Potapon-Pracaitis declares that whatever may be the quantity of gastric juice furnished at one given time, its proportion of pepsin from first to last is uniformly small if the animal has not received pepsinogens by mouth or anus; when the animal has received them, the juice, at first scarcely peptic, becomes finally rich in pepsin. Its amount varies with the amount of pepsinogenic substance that has penetrated into the blood. There is no relation between the digestibility of the food and the amount of pepsin which it calls forth. Dextrin, which has no need of digestion, makes the juice very peptic; meat bouillon also renders the juice peptic, while the coagulated white of egg, and corn-meal gruel, which require long digestion, provoke the secretion of a juice but slightly peptic or almost apeptic. Pilocarpine always causes an abundant flow of juice, the quality of which, however, depends on the condition of the animal. After a sufficient preparatory repast the juice is very poor in pepsin; after a medium repast the juice contains variable quantities of pepsin; after absorption of a septogenic substance, the juice is very rich in pepsin.—*Revue de Thérapeutique Médico-Chirurgicale*, September 1, 1901.

The Journal of Tropical Medicine, September 2, 1901.

Hours of the Day at Which the Rigor of Fevers Begins.—Edward Horder notes that in 388 observations made during the first six months of 1901, 46 per cent. of the fever cases developed rigors between midnight and midday, and 54 per cent. between midday and midnight. The truth is doubtless that the larger percentage of cases begin between 10 A.M. and noon, although a fair number do commence between 1 and 6 P.M. All the observations were made in males.

The Percentage Relation of Eosinophiles to Other Leucocytes. Edward Horder of Pakhoi, South China, says that the percentage of eosinophiles is usually given at 2 to 4. The blood of healthy Chinese assistants, nurses, teachers, coolies, etc., gave a percentage of 15, even 18 and 19. Europeans gave an average of 5 per cent., two only showing 6 and 8.5 per cent., respectively. Patients suffering with ulcers showed an average of 20 per cent.; those with chronic rheumatism, anæmia, eye diseases, and ordinary diseases of metabolism, an average of 22 per

cent.; one case of tuberculosis, 42 per cent.; malarial patients showed an average of 12 per cent., two giving 37.4 and 24.5, respectively. Among lepers 30 is the average, but 42 per cent. is found in many cases.

Malarial and Filarial Diseases in Barbados.—George C. Low states that indigenous malarial fever does not exist in the island. Neither were any *Anopheles* mosquitos found. In marked contrast to the absence of malaria is the prevalence of filarial disease, which is not to be wondered at, when one considers the extraordinary abundance of the common domestic mosquito of those parts, the *Culex fatigans*, which acts as an efficient host for the spread of the disease. Out of more than 600 blood examinations of people from all parts of the island only *Filaria nocturna* was found, and of 100 mosquitos examined, 23 per cent were found to be infected with *Filaria nocturna* at various stages of development, and in one, mature forms were found near the proboscis. The author urges the adoption of the same measures that are used to exterminate the *Anopheles* in order to rid Barbados of the *Culex*.

The Causation of Beriberi.—Max F. Simon suggests the following points for consideration in the chemical and other investigations conducted with a view of ascertaining the cause of this disease: 1. Proof of infectivity of beriberi blood serum. 2. A careful chemical analysis of beriberi blood, especially of the serum thereof, and comparison with the blood of healthy persons. 3. Comparison of conditions prevailing among bodies of men among whom beriberi breaks out, with those prevailing in communities where (or when) the disease does not break out, in respect of: (*a*) anything in environment pointing in the former case to opportunities for toxic formation which do not exist in the latter; (*b*) any differences in methods of cooking, time of serving out after cooking, materials used in cooking (pots, etc.), which might in the one case favor chemical changes in the food, but not in the other; (*c*) any other differences which may strike an observer as capable of producing effects in the direction indicated.

Clinical Department.

A CASE OF ACUTE MORPHINE-INTOXICATION PROMPTLY RELIEVED BY HYPODERMICS OF PERMANGANATE OF POTASSIUM.

By LEONARD WEBER M.D.,
NEW YORK.

Barker, Smith (1877), and Wm. Moor (1894), by their experiments and clinical experience, have made us acquainted with the antidotal properties of permanganate of potassium in opium poisoning. It is by the strong oxidizing power of this salt that morphine is reduced to oxydimorphine, which is comparatively harmless. A number of cases have been published during the last six years, in which the salt has been administered by the mouth or hypodermically, with positive results and without subsequent harm. The following, I believe, deserves to be placed on record:

A gentleman, aged thirty-eight, very stout, weighing about 250 pounds, with irritable heart, probably due to fatty overgrowth, had been subject to typical and atypical attaeks of gout during the last ten years. On the night of January 20, 1899, he had a gouty seizure in the big toe, and a most acute lumbago at the same time. The following morning between 6 and 7 A.M., the patient took either one or two morphine powders of gr. $\frac{1}{8}$ each—probably two. At 9.30 A.M. I found him still in great agony, clamoring for relief. There being no symptoms whatever of morphine action, I gave him, without further inquiry, morphine gr. $\frac{1}{8}$ hypodermically, remembering that I had administered as much as that to the patient without harm on previous occasions. At 10 A.M., he fell asleep and I left for home, but was sent for in haste at 11.15, the messenger saying that Mr. R. was either dead or dying. Reaching the house at 11.40, I found the patient lying in bed, head down, cyanotic, respiration having apparently ceased, with a very fast and small pulse, and the sweat pouring from him. After pulling him out of bed quickly and raising his head and lower jaw and slapping the body with cold, wet towels, the respiration began in Cheyne-Stokes fashion for about a minute, when it again ceased. At noon I injected permanganate of potassium gr. $\frac{1}{4}$, hypodermically, repeating this every ten minutes until gr. ii. had been given. The injections were made in the outer sides of thigh and loin; at one o'clock respiration and pulse were better, the patient was conscious and able to swallow a cup or two of black coffee. At 1.30 all danger seemed to have passed; at 2 I put him to bed; at 2.20 gave a hypodermic of strychnine gr. $\frac{1}{30}$, repeating it at 4.30. When I saw the patient again, at 7 P.M., he appeared to be quite comfortable. Neither local nor general sequelæ were observed. It is self-evident that in any severe case of opium poisoning the well-known mechanical and hydriatic means to keep respiration going, and stimulants to excite the central nervous system, must also be employed; it is also commendable to inject the permanganate salt hypodermically, though it may also be given by the mouth gr. i. to ii., in aqueous solution at a single dose every fifteen minutes until all immediate danger is passed.

A CASE OF DUCHENNE'S DISEASE; TEMPORARY TRACHEOTOMY; DEATH.

By H O SOMMER M.D.,
WASHINGTON D. C.
LATE ASSISTANT PATHOLOGIST METROPOLITAN HOSPITAL NEW YORK.

The following case I wish to publish more for the marked pathological conditions found than for its surgical interest. The patient was a German woman, aged fifty, and had been three months in the hospital. It was an old advanced case of progressive (spinal) muscular atrophy. I had seen the woman about a year before the admission. She had a positive syphilitic history, with perforation of the hard palate, etc. The case was diagnosed by Dr. O'Connor as one of bulbar paralysis. The patient had for some time been suffering from a difficulty in articulation, and even phonation and respiration. The difficulty in respiration became so great that my colleague, Dr. Leopold, assisted by myself, did a tracheotomy. After some days the tube was removed, as respiration had sufficiently improved. The wound healed well, and although phonation returned to a considerable degree, the power of articulation did not. The woman went through the usual course of the disease, becoming veritably a "living skeleton," but the details I will spare the reader, further than that her mind became so much impaired that she became a lunatic requiring confinement and restraint, during which time I had the privilege of observing her. This lasted for several weeks after tracheotomy till she came to me for "section cadaveris." The necropsy was done on July 9, 1898, and disclosed the following condition: The dura was very adherent, especially in the occipital region. The pia was much congested, especially occipitally. In spite of the utmost care it was not possible, as is usually the case in removing the brain, to remove it in toto by severing the cord just below the medulla, and closer inspection revealed decided softening, involving the pons, etc., at which point the brain had fallen apart. There was a large dark clot in the right lateral sinus; also a small dark clot in the left lateral sinus, extending considerably into the jugular vein, and a clot in the superior longitudinal sinus. In the heart I found a white clot in the aortic valve, and dark clots in the pulmonary artery and ventricles. The tracheotomy wound in the neck was firmly closed by strong adhesions.

1227 O Street, N W.

Society Reports.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Twenty-seventh Annual Meeting, Held at Put-in-Bay Island, O., September 12, 13, and 14, 1901.

The association convened in the assembly hall of the Hotel Victory, and was called to order at 10 A.M. by the Chairman of the Committee of Arrangements, Dr. J. C. Culbertson of Cincinnati, Ohio.

Prayer was offered by the Rev. C. H. Tucker of the Reformed Episcopal Church of Put-in-Bay Island, after which Dr. Culbertson made a brief report as Chairman of the Committee of Arrangements. Dr. W. C. Chapman of Ohio delivered an address of welcome.

At this juncture the President, Dr. A. H. Cordier of Kansas City, Mo., was introduced and took the chair. The reports of the Secretary, Treasurer, Committee on Credentials, and Committee on Publication were read and adopted.

Dr. H. O. Walker offered the following resolution, which was unanimously adopted: *Resolved*, That this association tenders to Matthew D. Mann and his competent confrères its congratulations on the prompt and masterly manner in which they have cared for the President, William McKinley.

President's Address.—This was delivered by Dr. A. H. Cordier. He selected for his subject "Some Phases of Nephrolithiasis." He drew the following deductions: 1. Hemorrhage from parenchymatous organs is, in most instances, easily controlled. 2. Nephrolithiasis is more prevalent than is generally supposed. 3. A stone having formed in the pelvis of the kidney, if too large to pass through the ureter, will sooner or later, produce symptoms demanding its removal. 4. Suppuration in stone cases is, as a rule, a late process and should be prevented by early surgery. 5. A wound in a healthy kidney heals rapidly. 6. Obscure, persistent pains in the region of the kidneys, in a patient who has had a renal colic years ago, should lead to an exploration of the kidney. 7. The operation of nephrolithotomy has a very low mortality. 8. The kidney should not be removed unless practically destroyed by the disease. 9. There exists a special cause for the development of stones in the right kidney. 10. With a carefully obtained clinical history, the diagnosis of stone in the kidney is usually easy. 11. At the time of operating the ureter should be explored, that its patency can be assured. 12. Post-operative patience and faithful effort on the part of the surgeon will result in the saving of many organs; otherwise removal will be necessary.

Fractures.—Dr. E. B. Smith of Detroit read a paper on this subject. He gave a résumé of the old and the new methods in diagnosing fractures. He said that fractures in each stage presented certain definite pathological surgical conditions. The diagnosis, treatment, prognosis, and complications with their medico-legal status were dwelt upon at length, and lesions examined, treated, and met by surgical experience. The recompense should be in keeping with the experience and surgical requirements.

Dr. Charles H. Hughes of St. Louis emphasized the importance of head symptoms in cases of fracture.

Dr. A. M. Hayden of Evansville said a joint that has a fracture into it should be kept quiet or immobilized for at least four or five weeks, so that the fragments may become thoroughly united and healed before resorting to passive motion. The latter procedure was used too early.

Dr. W. T. Stewart of Chicago spoke of suturing the fragments in fractures, saying he had been disappointed in using the various methods recommended in textbooks and journal literature, and expressed the hope that some member would speak of immobilization of parts in delayed union of fractures, and in fractures of recent occurrence.

Dr. S. S. Thorn of Toledo said one cause of delayed union in fractures was malnutrition, the result of enforced anæmia, and this anæmia was the result of applying bandages too tightly and the use of short splints, thereby causing constriction, which resulted in anæmia, starvation, and hence delayed union.

Dr. A. J. Ochsner of Chicago mentioned another cause of non-union of bone, namely, the interposition of muscle or fascia between the fragments, and cited cases in point.

Dr. A. M. Phelps of New York spoke of a third reason why union did not take place after a fracture of the thigh—the nutrient artery became ruptured, and thus nutrition was cut off. Treating fracture with coaptation splints was wrong. He favored extension (Buck) and fixation in fractures of the femur. A patient with a fractured femur is put to bed with Buck's extension applied for a week or ten days, until laceration of the soft parts has subsided, after which a brace is applied, the patient gets out of bed, is driven about in a carriage, and fed well.

Dr. Smith, in closing, stated that joints should not be immobilized for the length of time surgeons had been in the habit of immobilizing them; and that injuries of the head ought to be operated on more frequently than they are.

Floating Liver, with Report of a Case.—Dr. J. Henry Carstens of Detroit followed with a paper on this subject. Very few such cases, he said, had been reported. The condition was often associated with general ptosis of the abdominal viscera. The patient was a woman, aged forty, quite stout. A gradually developing tumor had been noticed, starting on the right side and growing downward. It was firm and non-fluctuating. On account of the distressing nervous symptoms, an exploratory cœliotomy was done, and the right lobe of the liver found enlarged and hanging down to the pelvis. It could be replaced in the normal position, and was stitched there. Recovery took place with disappearance of all the distressing symptoms.

Dr. Hayden reported a similar case.

Dr. Willis G. MacDonald of Albany had seen a considerable number of such cases. Some years ago he showed the lobe of a floating liver with a gall-bladder and some gallstones. He had seen two cases in which there was general ptosis of the liver, one in which, by change of position of the patient, it was quite possible to have had the liver float down beyond the border-line of the umbilicus, and, changing the position of the patient back again, have it disappear beyond the border of the ribs.

Sterilization of Rubber Gloves by Formaldehyde Gas, and the Use of Mild Antiseptics Inside the Gloves.—Dr. A. Goldsphon of Chicago made a preliminary report on this subject. In 1880, J. Geppert pointed out the mistake of exposing germs in their culture medium to any antiseptic; because the medium absorbing the antiseptic is spoiled for its purpose long before the germs are really dead, and a non-growth is then no proof of sterility. Since a number of health officers (not bacteriologists) have made tests involving this error, and have based on them rules for disinfection that are fallacious, the speaker said he had been induced to carry on a series of bacteriological tests to determine the minimum requirements for sterilizing rubber gloves by formaldehyde. He used small pieces of surgeon's silk as germ-carriers, because the gas would evaporate from them. With his experiments he determined that (1) a small connection with a chimney flue to afford a circulation of the gas in the sterilizer appears to be necessary, when the gas is generated by a lamp; (2) three hours was the minimum time needed for certain sterilization in his apparatus. A cross test was made by pouring culture material into the gloves afterward, and then heating it. Sterilized boric-acid powder was used as dusting powder inside the gloves to make them slip on dry and very easily, and about one-half ounce of 55 per cent. alcohol was then poured into each glove. The fluid in the gloves after operating one or more hours was tested

by culture in many experiments, and found sterile with one exception.

Infection from the Bacillus Ærogenes Capsulatus.—Dr. JULIUS H. JACOBSON of Toledo read a paper with this title, in which, after detailing some experiments and narrating observations, he deduced the following conclusions: 1. That infection from the bacillus ærogenes capsulatus occurs much more frequently than is recognized. 2. It dominates the whole field of pneumopathology. 3. Such terms as emphysematous gangrene, air embolism, emphysematous cellulitis, are misleading and vague, and should become obsolete. 4. Infection from this germ produces a rapid toxæmia; the formation of gas in infected areas, resulting in gangrene and death. 5. Its principal habitat is the soil and intestinal tract. 6. Owing to its wide distribution in the soil, the danger of infection in all traumatic cases should not be forgotten. 7. A probable diagnosis can often be made by the history, clinical course, and objective signs of the case. 8. A positive diagnosis can only be made by bacteriological examinations, cultural and animal inoculations. Simple stained specimens taken from the site of infection will often make the diagnosis.

Features Determining Permanency of Cure in Radical Operations for Hernia.—Dr. A. J. OCHSNER of Chicago followed with a paper with this title. Permanent success following herniotomy depended, he said, upon a comparatively small number of practical points which must be observed in order to secure satisfactory results regularly. These were: 1. The wound must heal primarily because suppuration resulted in an abundance of cicatricial tissue, and this was most unstable. 2. The stitches must not be drawn tightly in order to avoid pressure necrosis. 3. The edges of the wound to be united must be free from fat and other unstable tissues. 4. The wound should be supported by broad rubber adhesive plaster strips until healed. 5. The patient should be kept in bed two to three weeks. 6. After the operation abnormal intra-abdominal pressure should be eliminated by avoiding constipation, etc.

In *inguinal* hernia, (1) the entire sac should be removed. (2) it was especially important to remove all the loose tissue between the transversalis and internal oblique muscles on one side and Poupert's ligament on the other; (3) the upper portion of this canal should be closed with especial care; (4) a long, thin omentum, if present, should be resected.

In *femoral* hernia, the canal through which the sac protruded was a perfect ring, and consequently if the entire sac was removed this ring would invariably close, and there could be no recurrence. All meddlesome operations contemplating the closure of this ring caused a certain percentage of recurrences.

In *ventral* hernia, following laparotomy, the original layers should be laid bare, and then the corresponding layers should be carefully united. The author preferred deep silkworm gut sutures to be tied after each layer had been united separately with chromicized catgut sutures.

In *umbilical* hernia, the ingenious operation first described by Dr. W. J. Mayo of Rochester, Minn., consisting of an overlapping of the edges of the hernial ring from above downward, or from side to side, for a distance of one and one-half inches, had given complete satisfaction.

Severing of the Vas Deferens and Its Relation to the Neuropsychopathic Constitution.—Dr. H. C. SHARP of Jeffersonville, Ind., read a paper on this subject. He discussed the subject under three heads: 1. The law of heredity, influencing the formation of the character of intellect and will, and the controlling of the appetites and passions, and all the moral impulses, and the pathological conditions to which the mental and physical life are subject. The chief manifestations of this diathesis are chorea, hysteria, hypochondriasis, inebriety, imbecility, criminality, and insanity; and it includes in its subjects sometimes the most gifted, as Burns, Coleridge, De Quincey, and others. 2. The rapid progressive increase of this diathesis, in the face of the efforts of medical sociologists and penologists. 3. The severing of the vas deferens as the means of stamping out this diathesis. The author outlined the field of the operation, the preparation for, and method of operating.

Dr. A. J. OCHSNER had removed the vas deferens in a number of tuberculous cases since his first operative work on defectives and criminals, and in no case has there been any disturbance of the ability of the patient to enjoy sexual intercourse.

Morbid Conditions of the Upper Respiratory Tract Resulting from the Infectious Diseases.—Dr. CAROLUS M. COBB of Boston gave a résumé of the autopsies reported by Wolff, Pearce, and Zuckerkandl. These autopsies showed that the involvement of the nasal accessory sinuses during the course of the fatal cases of diphtheria, scarlet fever, measles, and influenza was the rule rather than the exception. He then showed from an analysis of 102 cases of nasal or postnasal catarrh without nasal obstruction, that 69 per cent. of these cases could be traced directly to one or more attacks of the infectious diseases. He called attention to the danger to the ears of treatment, during the height of the primary disease, by means of douches and sprays, and drew the following conclusions: 1. The importance of the so-called catarrhal inflammation of the upper air tract, not only in relation to local disease, as catarrhal inflammation of the middle ears, the eyes, the larynx, and the bronchial mucous membrane, but to general systemic infection as well. 2. Nasal obstruction does not cause a catarrhal discharge, *per se*. 3. The frequency with which the accessory sinuses are involved in the infectious diseases. 4. The neglect of the diagnosis of this involvement of the sinuses, either during the course of the primary disease, or during convalescence. 5. The hypertrophy of the glandular tissue in the throat and nose following the infectious diseases. 6. The persistence of the Klebs-Loeffler bacilli in the secretions of the nose, which may be a serious menace to the public. 7. A large percentage of the cases of catarrhal disease, *i. e.* when the complaint is of a nasal or postnasal discharge, which can be traced to the infectious diseases. A table accompanying the paper showed that 69 per cent. of the catarrhal cases could be directly traced to some one of these diseases.

Dr. L. H. WARNER of New York dwelt on the importance of paying more attention to the digestive organs in looking for the causes of diseases of the respiratory tract.

Dr. WM. F. BARCLAY of Pittsburg thought a great deal of harm was done by the neglect of conditions of the air passages following diphtheria, scarlet fever, and other diseases, and much good would be effected if the contents of Dr. Cobb's paper could be widely made known among general practitioners. While agreeing generally with all the author had said, he attached more importance to local in conjunction with general treatment.

Dr. J. HOMER COULTER of Chicago said the important point to be kept in mind was that constitutional treatment should never be neglected.

Dr. EMIL AMBERG of Detroit remarked that in affections of the ears it was better to let the pus escape to the outside than run the risk of its getting into the food, as frequently happened in the case of children.

Dr. JOHN NORTH of Toledo thought it a mistake to speak of catarrhal troubles as inflammatory. In fact, the ideas of the profession had undergone such a change in regard to inflammation that it would be well if all the textbooks on the subject could be destroyed and someone were to write an entirely new work on the subject.

Dr. A. E. STERNE of Indianapolis considered that Dr. Cobb as a nose and throat specialist was to be commended for the broad view he had taken of the subject.

Dr. Cobb, in his reply, said there was no finality in the conclusions which he had suggested. His principal object was to encourage observation with the view of establish

ing the effects on the air passages produced by different diseases

Acute Intestinal Autointoxication.—Dr. JOHN M. BATTEN of Downingstown, Pa., read a paper on this subject, reporting an illustrative case. He was called to see professionally W. F. B., aged fifty-six years, on February 21, 1898. The patient had been suffering with exhaustion for several days, although neither his pulse nor his temperature was disturbed. He ordered him to bed, thinking that rest there might be beneficial to him. Within forty-eight hours, on his own account, the patient took a dose of calomel, which still further prostrated him, so he had to be assisted to bed from the chamber. Dr. Batten noticed that the patient had had a gray, leaden complexion for several weeks preceding his first call. That gray or cachectic complexion is usually pathognomonic of intestinal autoinfection, although it may indicate malignant disease of the liver. In fact, for several days after his first visit, it was his opinion that the case was one of malignant disease of the liver, as there was a congestion or thickening of the lower end of the stomach and upper end of the duodenum. The patient was corpulent, weighing 220 pounds, and lost forty pounds during the two months he was confined to bed. Previous to his ailment, the man had been careless in securing a regularity in the movement of his bowels for some months. The usual symptoms presented themselves, constipation, flatulency, borborygmus, urates, and the constituents of the bile in the urine, fever, headache, unpleasant dreams, and melancholia. The treatment consisted of large daily doses of calomel until the bile flowed freely, then antiseptics internally, together with small doses of mercury, until an amelioration of the symptoms was effected, then the natural mineral waters, followed by vegetable tonics in connection with hot baths. For a weak heart, with which he suffered, strychnine was prescribed. Nitrate of silver and small doses of mercury were given for relief of the congestion of the lower end of the stomach and upper end of the duodenum, which was thought to exist. The diet was beef essence, but the patient did not exhibit a disposition to eat. His legs swelled during convalescence, and he suffered acute pain in the knees. In due time the patient fully recovered his health, after a protracted stay at Mount Clemens, Michigan, whence he had gone as soon as he had convalesced sufficiently to enable him to do so.

Dr J. A. STUCKY of Lexington, Ky., said the idea was becoming more and more prevalent that autointoxication of the intestines was due to a disturbance of metabolism, whatever that might mean, within the intestinal tract. Whatever the cause, the treatment seemed narrowed down to the one word, "elimination."

Dr. I. N. LOVE of New York said that, while elimination was all-important when the autoinfection had been produced, it was at least equally necessary to guard against its production. Overeating was the principal evil to avoid in this connection.

Dr. GEORGE D. KAHLO of Indianapolis insisted on the importance of giving the digestive organs absolute rest when autoinfection was found to exist. It was wonderful how long a person could live simply on air and water, and in cases of the kind so-called starvation was of the greatest efficacy.

Dr. WILLIAM BAILEY of Louisville thought a mistake made in modern times was to relieve the digestive organs too much of the functions which they were intended by nature to discharge.

Dr. NORTH remarked that the regulation of the diet would be sufficient for all purposes if they could start far enough back. This, however, they could not do, for the mischief was already done before the patient presented himself. It was to be feared that even doctors did not regulate their diet to the extent that was desirable.

Dr. BARCLAY condemned the practice now too common of using a syringe daily to prevent constipation. While the cleaning out of the system by this means was of great use in an emergency, the habitual use of the syringe did as much harm as the habitual use of purgatives.

The discussion was continued by Dr. G. W. McCaskey of Fort Wayne, Ind., Dr C. S. Chamberlain of Cincinnati, Dr. C. H. Hughes of St. Louis, Dr. Sterne, and others, the relation of the nervous system to the digestive and other organs being the branch of the subject dealt with by Dr. Hughes, and Dr. Sterne remarking that it was difficult to say which set of speakers had the best of the argument, because of the vicious circle which the condition in question had established, making it impossible to distinguish between cause and effect.

Asthma.—Dr. JOHN NORTH of Toledo, Ohio, in a paper with this title, said that a great many theories had been advanced as to the etiology and pathology of asthma; among them, reflex neuroses, contraction of the bronchial tubes, nervous spasm, blood disease, irritation of the air tubes, irritating tumors, extension of bronchitis, vasomotor bronchitis, diathetic neuroses, neuroses of the pulmonary plexus, uric-acid diathesis, oxalic-acid dyscrasia, an excess of venous blood in the medulla, etc. Most of these theories contained a small grain of truth, but no one of them could account for the asthmatic paroxysm. Three factors were required for the production of asthma. These, the so-called "asthmatic tripod," were as follows: (1) A vulnerable area of mucous membrane, (2) an abnormally sensitive nerve center, and (3) an external irritant or exciting cause. If all these three factors were present at any one time, an attack of asthma would occur. No two of them could produce an attack; all three were required, and if one of them were removed, the attack of asthma would not return.

The first factor for the production of asthma may be situated in the nose, nasopharynx, pharynx, larynx, or bronchial tubes. The various names given to the different varieties of asthma are derived from the locality of the vulnerable area of mucous membrane. The second factor may be either inherited or acquired. The neurotic element in asthma has been observed by all writers. Uric acid, oxalic acid, and the oxalates may produce abnormality in the nerve centers. The third factor is difficult to determine in some cases, as we may have a number of irritants and exciting causes.

In the treatment of asthma, attention must be given to the three factors necessary to produce asthma. The treatment is divided into that of relieving the paroxysm of dyspnœa, and treatment during the interval to prevent their recurrence. The relief of the paroxysm may be accomplished by remedies that relieve either of the three factors mentioned. The treatment during the interval must be applied permanently to relieve one or more of these factors. The treatment varies according to the conditions in each case. Asthma can be cured if treatment is scientifically instituted and carried out.

Dr. WARNER spoke of the necessity of having an examination of the blood as well as of the urine.

Dr. PORTON R. BENNETT of Daytona, Florida, said he cured all cases of asthma that came to him by means of iodide of potassium and tincture of belladonna. Other speakers advocated the use of alkalies, but the majority adhered to the opinion that no one treatment was suitable for all cases, the causes of asthma being numerous, and each calling for a different remedy. Among those who spoke were Dr. Wm. A. Dickey of Toledo, Ohio; Dr. C. T. Stewart of Chicago, Dr. Batten, and Dr. Chamberlain.

Address in Medicine.—This was delivered by Dr. FRANK BILLINGS of Chicago. He selected for his subject, "What Are the Qualifications Necessary for the Success of the Practice of Medicine?" He said that the qualifications of success, in any walk in life, depended upon the meaning of the word success. Not uncommonly success meant to the majority of mankind the acquisition of wealth. Without a living income, life was too full of anxieties to allow one to do good work. The average physician, said the

speaker, probably received less compensation for his services than any other member of society, when one considered the time and money spent in preparation, the responsibilities assumed, and the character of the service rendered to the patient. To-day the problems in medicine were so profound that a good preliminary education was necessary to enable the student to pursue the study of medicine rationally and successfully. While a college or university education might not be essential to prepare one fully for the study and comprehension of medicine, still it gave one broad culture, a discipline of mind, which added to the pleasures of life of the practitioner, if it did not bring him material advantage.

The successful doctor must be industrious, thorough, painstaking, and methodical in all he does. One of the best evidences of a successful practitioner was the constant effort to make a diagnosis.

Spinal Deformities.—Dr. A. M. PHELPS of New York discussed the subject of tuberculous disease of the spine, lateral curvature of the spine, and the proper treatment of each.

Congenital Valvular Obstipation.—Dr. THOMAS CHARLES MARTIN of Cleveland read a paper on this condition, which, he said, was the result (1) of embryological hyperplasia or overgrowth of the rectal valves, which was characterized by an abnormal depth of the valve, or (2) to such anatomical propinquity of two valves that they overlap and establish under the pressure of the descending force a temporary diaphragm. The symptoms were more or less straining for defecation of solid or semi-solid fæces, which developed at an early period and continued.

Varicose Veins and Their Treatment.—Dr. J. LIVELY JOHNSON of Louisville, Ky., read this paper. Varicose veins of the first degree were of little importance, aside from the mental anxiety of the patient, but as the varicosity advanced, the veins assumed a more grave character and were often a source of annoyance to both patient and surgeon. A varicosity might exist in any part of the body. This condition of the veins was found most frequently in certain localities, as the pampiniform plexus and in the veins of the foot, leg, and thigh. One of the greatest dangers to the patient suffering from varicose veins was the danger of a sudden rupture, with perhaps a fatal loss of blood. Inflammation and thrombosis might frequently occur. This pathological condition incapacitated one for a position in the army or navy, thus debarring him from participating in the advantages offered by government positions. The sufferer was also debarred from participation in all athletic sports. In this enlightened age, it seemed strange that physicians still allowed patients suffering from varicose veins to pursue the even tenor of their way, with only a smear of oxide of zinc ointment, and a roller bandage applied to hold it in place. The rubber stocking was also a failure; aside from its inability to support the blood column, it became soiled and rancid from perspiration, producing an annoying dermatitis. This line of treatment did not cure, consequently the treatment had to be persisted in as long as the patient lived. The only rational line of treatment to be pursued in the management of varicose veins was to remove completely by extirpation the entire diseased vessels. Temporizing with varicose veins not only did the patient great harm, but brought reproach upon the surgeon. The surgeon had the choice of a number of operations for the radical cure of varicose veins of the lower extremity. He must be able to adapt the surgical procedure to the case in point. He only mentioned the operations that might be employed. Ligation might be used, or Schede's technique might be resorted to. Phelps' excision of limited portions of the diseased veins was a good operation and might be frequently used with success. The most radical form of treatment consisted in complete extirpation of all diseased veins. Under no circumstances should any operation be performed upon veins without the most stringent aseptic precautions, thus preventing serious after-consequences.

The Use and Limitations of the Elastic Ligature in Intestinal Surgery.—Dr. THEO. A. MCGRAW of Detroit presented a paper with this title (see p. 521).

Dr. H. O. WALKER of Detroit reported cases of intestinal resection and approximation by the Connell suture, and contrasted it with other methods of approximation. He spoke highly of this suture, and recommended its use.

The Surgical Features of Typhoid Fever and Dysentery were considered by Dr. HAL C. WYMAN of Detroit. He held that early operations for perforation in typhoid fever gave the best results. Physicians should anticipate perforation and intestinal hemorrhage in typhoid fever of a severe type by surgical operation, which promised to heal the ulcerated bowel before it perforated or bled. In severe cases of a threatening type, the author said, why not open the cæcum near the ileocæcal valve, establish a fistula through which a tube might be passed cautiously into the ileum and the ulcerated region daily washed with normal salt solution until it healed, and also the colon to rid it of infecting bacteria? When the patient was convalescent, the fistula would close spontaneously.

Some Indications for Gastroenterostomy.—Dr. WILLIAM J. MAYO of Rochester, Minnesota, read a paper with this title, his conclusions being based on a personal experience derived from sixty-four operations. In malignant disease, gastroenterostomy was indicated only if symptoms of obstruction were present. The mortality was high, 25 to 30 per cent. The writer lost four out of sixteen cases. The reason for this mortality lay in the bad condition of the patient. The early cases in good condition needed radical treatment, and the latter operation (pylorectomy, etc.) on this account had an even lower mortality than gastroenterostomy, which had no such limitations.

For open ulcer, gastroenterostomy was of the greatest benefit if the ulcer was situated near the pylorus, and it usually was. Under such circumstances, the stomach was of normal or increased size, the latter condition being due either to obstruction or pyloric spasm. If the ulcer be distant from the pylorus and the stomach contracted, gastroenterostomy had less value and the anastomotic opening might close, although the ulcer was usually healed before this took place. The writer had had thirteen gastroenterostomies for open, intractable ulcer, with one death.

For benign obstruction without regard to origin, gastroenterostomy was the operation of choice, the cure being immediate and lasting. Pyloroplasty enlarged the outlet, but if the stomach was very large and pouched, the degenerated muscle fiber might fail to elevate the food to the pylorus and relief was not always afforded. Gastroenterostomy drained from the lowest point, and was superior in every way to the plastic operation. In thirty-five gastroenterostomies of this class only one patient died.

Appendicitis.—Dr. WM. J. GILLETTE of Toledo read a paper in which he reported one hundred cases operated on for appendicitis.

Suture of the Abdominal Wall.—Dr. CHARLES DAVISON of Chicago said that the main point in this procedure was closure of any laparotomy wound by suturing each layer with continuous silkworm gut suture, the ends of which are left out at the angle of the wound, to be removed when healing has occurred. The suture in the strong fascia is tied in position at each end in the fascia with a knot that can be unlocked by traction on the exposed ends when the stitch is to be removed. The advantages of the method were: 1. Certainty that all suture or ligature material placed in the wound has been made sterile by boiling in water. 2. Accurate layer approximation of tissue. 3. Removal of the buried sutures when healing is complete. 4. Capillary drainage from each layer. 5. Safety of intestines from injury during the application of the sutures. 6. Rapidity of application.

7. Minimum line of irritation on the peritoneal surface and consequent adhesion to viscera. 8. Slight scar in the skin, there being no perforation of the skin by sutures. 9. All of the advantages of a permanent buried suture without the danger of future irritation and extrusion. 10. The advantages of an absorbable suture without the danger of sepsis from the suture and without producing a nidus for septic germs from the blood current during absorption.

Dr. TRUMAN W. BROPHY of Chicago demonstrated some cases of surgery of the palate by the aid of stereopticon views.

Dr. M. L. HEIDINGSFELD of Cincinnati discussed some causes of ignored syphilis and their remedies, and gave clinical examples.

Hæmatology.—Dr. L. H. WARNER of New York City spoke of the imperfect methods of obtaining blood from patients for microscopical examination, and said that the subsequent incorrect methods of fixing and staining specimens had frequently caused errors, the results being of no value as an aid to diagnosis. The incorrect understanding as to the physiological action of the electro-saline halogen derivatives (iodine, bromine, chlorine), especially as to the amount resorbed (chemical uranalysis), had caused leucocytosis to be wrongfully attributed to other causes. The blood in infectious diseases, if properly obtained and examined on the hot stage, showed certain histological changes in the red cells, also certain staining affinities which enabled the hæmatologist to arrive at an early diagnosis in cases of syphilis, carcinoma, etc.

Hay Fever.—In a paper on this subject, Dr. A. D. MURPHY of Cincinnati said three conditions were necessary to produce the complaint, namely, depleted nerve centers abnormally sensitive to uric acid; abnormal condition of the nasal cavities, and atmospheric and climatic conditions. Consequently, to effect a cure it was necessary to eliminate the uric acid, restore the depleted nerve cells to their normal condition, and relieve the effects. Hot baths and exercise and the careful selection of food were all of importance. As regards medication, he relied principally on a combination of arsenic and solution of gold, supplementing it with local applications of the suprarenal extract or its active principle, adrenalin.

The paper was discussed by Drs. North, Cobb, McCaskey, and others.

Scientific Aids to Diagnosis.—Dr. HENRY D. HOLTON of Brattleboro, Vt., read a paper with this title. Passing over percussion and auscultation as a means of examining the heart and lungs, and simply mentioning the importance of making chemical and microscopical examinations of the urine in cases where the symptoms indicated an abnormal condition of the kidneys, and also those in which the symptoms were vague and uncertain, he proceeded to refer at length to an aid that had not found general favor with the profession, to wit, the use of the ophthalmoscope in many affections of the brain and spinal cord, in which he contended it had been proved to be of great value. He also spoke of the help to be derived from the examination of the blood.

Dentist's Neck.—Dr. ALBERT E. STERNE of Indianapolis described a hitherto undescribed neurosis to which he gave the name of dentist's neck. When it first attracted his attention he thought the affection was unique, but he had since come to the conclusion that it was by no means rare, and that it sometimes attained the dignity of seriousness to the afflicted individual. As to the pathology of the affection, he admitted that he had to rely largely on conjecture. He believed that it was in many respects analogous to other occupation neuroses, not only in its etiology of regionary overstrain, but also in its cerebral functional character. In all these complaints he considered the peripheral manifestations as secondary to the localized brain-cell fatigue.

Necessity of and Indications for the Bed-Treatment of the Insane.—Dr. F. P. NORBURY of Jacksonville, Ill. read this paper. In its incipient stage, he said, insanity responded readily to treatment, hence the importance of early recognition and appropriate treatment.

Puerperal Insanity.—Dr. HAROLD N. MOYER of Chicago read a paper on this subject.

Suprarenal Extract.—Dr. JOKICHI TAKAMINE contributed an account of his discovery of the active principle of the suprarenal gland, to which the name of adrenalin has been given. He also explained the mode of preparing the drug. Dr. Cobb, Dr. North, Dr. McCaskey, and Dr. Charles F. McGahan bore testimony to the value of the preparation.

Indian Contributions to Therapeutics was the subject of a paper by Dr. B. T. WHITMORE of New York. He showed that the modern so-called Indian remedies have no connection with any system of medication practised by the aboriginal Americans.

The Dyspeptic's Diet.—In a paper thus entitled, Dr. GEORGE D. KAHLO of Indianapolis contended that diet was a more important therapeutic agent than medicine. Perfect nutrition was of primal import, and could only be maintained by a mixed diet, in which there must be a proper proportioning of the elementary food substances.

Personal Element of Error in Therapeutics.—Dr. GEORGE F. BUTLER of Alma, Mich., read a paper on this subject. Personal elements of error are accepted, he said, in all the exact sciences, not excluding astronomy. In medicine this element does not receive allowance, except to some slight degree in histology, pathology, and neurology. It is practically neglected in therapeutics. This is due to the crude, empirical methods employed, and the lack of judicial training. The personal element leads to the eulogy of worthless remedies and the ignoring of unusual effects of beneficial ones. The early but ignored recognition of the uselessness of sarsaparilla by Weir Mitchell illustrates this. Only the recognition of this personal element can render therapeutics scientific. The elements involved are proper diagnosis, not merely of the disease, but of its type, recognition of individual peculiarities of the patient, recognition of the proper preparation of the remedy, recognition of its untoward effects, and, finally, recognition of the fact that pathologic states indicate a new force introduced into the organism which disturbs its balance.

The Acquirement of Nervous Health.—Dr. F. SAVARY PEARCE of Philadelphia discussed the pathogenesis of nervous and mental diseases, and from the standpoint of salient signs and symptoms of the so-styled "nervous breakdown" in the earlier periods of development. Insistence was made upon the urgent necessity of more serious recognition by the profession of the points elucidated in the paper, if the wear and tear of modern exacting American life is to be forestalled in its baneful influence upon the acquired nervous temperament of many, and of business men in particular, in the temperate zone of the United States. Cases cited, and good results given.

Tuberculosis.—A short symposium on this subject was introduced by Dr. CHARLES F. MCGAHAN of Aiken, S. C., who dealt with the treatment of the disease in the patients' homes. He was followed by Dr. HOWARD of Champaign, Ill., who reported favorably on the treatment of tuberculosis with formaldehyde and its salts. Dr. WILLIAM A. DICKEY of Toledo, Ohio, who read the third paper in the series, spoke on the attitude of the profession toward the public and the individual suffering from tuberculosis.

The Evil Effects of Alcohol were discussed in papers by Drs. T. D. Crothers of Hartford, Conn., and T. B. Greenley of Meadow Lawn, Ky.

Autointoxication and Its Treatment.—Dr. CHARLES H. SHEPARD of Brooklyn, in a contribution on this subject, entered a plea for the more general use of Turkish baths.

The Female Pelvis.—Dr. Ernest Gallant of New York made some observations based upon a study of the female pelvis.

The Appendix Vermiformis.—Dr. N. Stone Scott of Cleveland showed stereopticon slides from original photographs, illustrating the anatomy, embryology, histology, comparative anatomy, and pathology of the appendix.

Address in Surgery.—Dr. Reginald H Sayre of New York delivered this address. He reviewed the status of surgery during the past, and noted the changes that have taken place in men, methods, and modes of thought, and speculated on the position which surgery would attain during the next one hundred years.

Election of Officers.—The following officers were elected for the ensuing year. *President*, Dr. S. P. Collins of Hot Springs, Ark.; *First Vice-President*, Dr. J. C. Culbertson of Cincinnati, Ohio; *Second Vice-President*, Dr. Paul Paquin of Asheville, N. C.; *Secretary*, Dr. Henry E. Tuley of Louisville, Ky.; *Treasurer*, Dr. Thomas H. Stucky of Louisville, Ky.

The Death of the President.—The following resolutions were adopted: "Our President is dead. Our President, who accomplished the unification of our country; the abolition of sectional lines; the expansion which made us a world-power, his last public utterance being in favor of peace, international reciprocity and sympathy, has been removed by the enemies of society.

"We are overwhelmed with sorrow and personal grief for the death of the greatest of the world's rulers; for one who, from the standpoint of statesmanship, political foresight, sympathy with all the people, morality, the sweetest features of personal character and home life, appealed to the appreciation of and affections of every citizen.

"A professional sorrow and disappointment has taken the place of a hope that had inspired us from the first day the nation's calamity overwhelmed us.

"Joining in the personal grief and bereavement from which every true and loyal American citizen is this day suffering, we, the members of the Mississippi Valley Medical Association, in our twenty-seventh annual meeting assembled, do postpone the further presentation and consideration of special papers, in token of the love and respect with which we shall ever cherish the memory of our martyred President, William McKinley.

"(Signed) Andrus Timberman, M.D.,
"H. O. Walker, M.D.,
"I. N. Love, M.D.,
"Committee."

On account of the death of President McKinley, a motion was made and unanimously adopted by a rising vote, that the papers listed for the third day be read by title, referred to the Committee on Publication, and that the association adjourn out of respect to the distinguished dead.

The association then adjourned, to meet in Kansas City, Mo., 1902.

A Study of the Insanities of Adolescence.—William Pickett after an exhaustive study of 344 cases of insanity occurring between fifteen and thirty years of age, carefully tabulated with reference to alcoholism, heredity, and kind of insanity, concludes that to classify insanity cases, probably the best plan is that followed by Dr. Dercum, to divide the insanities into the conventional forms of mania, melancholia, etc., then to discuss the cases in their relation to periods of life, childhood, puberty, adolescence, the menopause and senility.—*The Journal of Nervous and Mental Disease.*

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Fourteenth Annual Meeting, Held at Cleveland, On September 17, 18, and 19, 1901.

First Day—Tuesday, September 17.

The association met in the banquet hall of the Hotel Hollenden, under the presidency of Dr. W. E. B. Davis of Birmingham, Alabama.

An address of welcome was delivered by Dr. C. H Hoover of Cleveland, to which a fitting response was made by President Davis.

Tubo-Abdominal Pregnancy.—Dr. William H. Humiston of Cleveland reported this case. The principal point of interest were. (1) Extreme loss of blood and shock pulse, 180, barely perceptible over radials; temperature 95° (2) The prompt result of submammary injections of sterile deeinormal saline solution at the time of beginning anæsthesia. These injections were recommended in desperate cases. (3) No attempt was made to remove the large amount of blood filling the abdomen close to the pelvic brim. The large amount of blood gave no trouble, and was taken care of and absorbed by the peritoneum rapidly.

Cornual Pregnancy; Rupture in the Fourth Month; Operation; Recovery.—Dr. Miles F. Porter of Fort Wayne, Indiana, followed with a paper with this title. The author saw Mrs. H., sixteen hours after she had been taken sick with severe abdominal pain accompanied by the usual signs of severe hemorrhage. She had had one living child and one miscarriage, and was near the middle of her third pregnancy Hasty examination revealed nothing abnormal in the vagina save a slight bloody discharge. Cœliotomy was immediately done, and a ruptured cornual pregnancy of about four and a half months with bicornate uterus, was found. The belly was filled with blood. The ruptured cornu was amputated, and the stump sutured, leaving the ovary and tube attached to the stump. There was profound depression, which was treated by saline rectal injections, and hypodermic administration of digitalin and strychnine. Recovery was uneventful. A large quantity of warm sterile water was left in the abdomen. The intact cornu was much enlarged and attached to the ruptured cornu with a rather long pedicle. The gestation sac was thick, save at the point of rupture, and was composed of uterine tissue. There was no communication between either the sac and the vagina or the tube and the sac. These communications became occluded subsequent to the impregnation A decidual membrane was present. The presence of this membrane marks the case as one of ruptured pregnancy in an illy developed cornu of a bicornate uterus. In tubal and interstitial pregnancy there is no decidual membrane in the sac. An abnormally low implantation of the tube and round ligament accounts for the fact that in this case they were attached to the outer side of the stump left after removal of the sac, and not to the sac itself, as is the rule. As a rule, pregnancy in a bicornate uterus terminates normally. In three of the cases, including his own, referred to in the author's paper, normal pregnancies preceded the rupture four times. In the others, no reference as to the other pregnancies was made. He had been able to find reports of but eighteen cases of ruptured cornual pregnancy, which, with his own, makes nineteen cases reported to date. The symptoms are those of ectopic pregnancy, save that the rupture occurs later in cornual pregnancy, and the hemorrhage is usually more profuse. A previous history of sterility or of tubal infection points to tubal rather than cornual pregnancy.

These two papers were discussed jointly. The discussion was opened by Dr. Edward J. Ill of Newark N J., who endorsed the treatment employed by Dr Humiston in his case, and said the quicker an operation is done in such cases, and the sooner the abdominal cavity

was walled [illegible] the chances for recovery of the patient. He agreed with Dr. Humiston as to the quantity of normal salt solution that these patients will receive and also that Murphy's method materially in the absorption of the fluid.

Dr. Edwin Walker of Evansville, Ind., referred to the indications for the use of normal salt solution in the abdominal cavity. He could not see what benefit was derived from the use of normal salt solution in the case of Dr. Humiston, for the reason that there were well-organized clots, and these could not have been acted by it. Such clots, when organized, became dried and were absorbed, and the salt solution only aided in the absorption of any septic material that might be present. He believed it was a mistake in all cases to wash out the abdominal cavity with salt solution. By wiping out the cavity with dry gauze it could be made clean, if it was not infected.

Dr. M. Rosenwasser of Cleveland commended the use of salt solution as follows in the case of Dr. Humiston, but expressed doubt as to the value of salt solution in the abdominal cavity. He had not seen any special beneficial change either in the pulse or condition of the patient by leaving saline solution in the abdominal cavity, or packing the extraperitoneal cavity that was left, he used sterile gauze in perfect iodoform gauze.

Dr. Herman E. Hayd of Toledo disagreed with Dr. Rosenwasser that the saline fluid was not absorbed. He had filled the pelvic abdominal cavity with normal salt solution, using two stitches only, and in an hour and a half the [illegible] was apparently vomited by [illegible] extraction.

Dr. Rosenwasser did not wish to be understood as saying that the fluid was not absorbed, but that it was not really absorbed [illegible] the peritoneum was in a pathological state.

Dr. J. Henry Carstens of Detroit stated that the use of normal saline solution in the abdominal cavity prevented, to a large extent, agglutination of the intestines and omentum. This cavity could be cleaned out just as effectively by sponging as by washing it out with salt solution. The drier the surgery was kept, the better the chances for agglutination. He preferred the use of sterile rather than iodoform gauze.

Dr. James F. Baldwin of Columbus, Ohio, said he had been disappointed in the use of normal salt solution, whether injected into the subcutaneous tissue or poured into the abdominal cavity and left there to be absorbed. He had used salt solution again and again, and it seemed to him absolutely inert. He had never seen it produce a particle of benefit.

Dr. Charles Greene Cumston of Boston stated that, given a condition as it either was in when an operation was undertaken for ruptured tubal pregnancy, he did not think the peritoneal cavity nor the subcutaneous cellular tissue had a sufficient degree of vitality to be able to absorb the salt solution in the majority of cases. Furthermore, in cases where the surgeon injected salt solution into a cavity whose walls were the seat of a pathological change he did not believe that the walls of that cavity would absorb the liquid. The only value that he could see in the normal salt solution was after a prolonged intra-abdominal operation, in which the intestines had been exposed, and the loss of heat had been great and the surgeon desired to introduce a certain amount of heat into the abdominal cavity. On the other hand, the use of gauze sponges in wiping out the debris should be extremely limited, because gauze would remove the epithelial covering of the peritoneum of the intestine and of the parietal peritoneum, and this he believed was a fertile cause for adhesions after operation.

Dr. Edwin Ricketts expressed great disappointment in the use of decinormal salt solution. He believed the results of its subcutaneous use had been overestimated. As to wiping out the abdominal cavity vigorously with a sponge, this was disastrous to the patient. Gauze should be pressed in and out without any marked friction of the peritoneum. No remedy had as yet been found equal to the judicious use of strychnine to overcome shock.

Dr. Humiston, in closing on his part said the abdominal cavity in his case was almost completely filled up with blood to the under border of the liver, and if he had attempted to handle the intestines and delay operation for the length of time it would take to cleanse the abdominal cavity of blood, he believed he would have lost his patient. He did not believe in irritating the peritoneal surface with dry gauze, as it injured it, and would often prove disastrous to the patient. He used iodoform gauze wrung out of hot sterile saline solution, thus washing the excess of iodoform out of it.

Transverse Incisions in Abdominal Cœliotomy.—Dr. Charles Greene Cumston of Boston read a paper with this title. For the last eighteen months he had been opening the abdomen in many of his gynæcological cases by a transverse incision, with a view to securing a more solid closure than he believed could be obtained by a through-and-through incision. The first incision, which he had now made forty-five times, is made at the upper limit of the pubic hair transversely, following a line parallel to the upper limits of the pubic hair making it about a centimeter below the base of the hairy triangle. The skin and cellular tissue are cut through until the fascia is reached, the upper border of the wound is then rapidly dissected off the fascia by a few snips of the scissors, and is then held up by a retractor. The lower border of the wound is also dissected off and drawn down by a retractor so that the incision becomes elongated, and if proper traction is made on the retractors by the assistant, a rectangular wound can be made sufficiently large to incise the fascia vertically to the extent of five or six centimeters. When incising the fascia, he thought it better to choose one the inner border of one or the other recti. When the belly of the muscle has been freely exposed, its inner border is found, and the whole muscular mass pushed aside, thus exposing the thin fascia underneath, without wounding the fibers of the muscle in the slightest. After the peritoneum has been opened, the retractors holding the skin-flaps back can be removed and ordinary abdominal retractors can then be employed. Through this transverse incision he had performed total hysterectomy with ease, and had done most of the ordinary work on the tubes and ovaries through an incision in the fascia not exceeding six cm. in length. He had enucleated an intraligamentous fibroid the size of a fist through this incision without experiencing any difficulty whatever. He also described another incision which he had employed nine times during the past two months with great satisfaction.

Dr. Edwin Ricketts could not agree with the essayist that the incision recommended by him was more advantageous than a median incision, or, in a case of single pus tube, even an opening on one side. In fact, some operators now did not select a median incision, but made an incision either to the right or left.

Dr. J. Henry Carstens saw a general surgeon make a transverse incision in performing a gastroenterostomy for the removal of the gall-bladder, but he had great difficulty in bringing the muscles and fascia together on account of the tendency to retraction. He thought the incision described by the essayist might prove advantageous for the removal of small tumors where an extensive operation was not needed.

Sarcoma of the Breast.—Dr. Edwin Ricketts of Cincinnati, after referring to the literature of the subject, reported two cases. The first patient was Mrs. McS., aged sixty-four, married, mother of three children. Thirty years before, and at the age of thirty-four years, she first noticed a hard, round, small lump in her right breast. Eight years after this she called the attention of her family physician to it, exacting a promise from him

that he would tell no one. This was twenty-two years before its removal. He advised non-interference. The essayist was called to see the patient in May, 1897, in January before, she had an attack of influenza, and was greatly prostrated from its effects, and from this time the tumor grew rapidly, being nearly the size of a child's head On his visit he found her with a tumor of the right breast that was about as ugly and vicious looking a growth as he had ever beheld. The cancer was as large as a navel orange, from which a dark sanious fluid was discharging. It was so large that the right arm was forced to project well out from the body. Temperature and pulse were normal. After drying out the cavity, it was packed full with 5 per cent. carbolic gauze. The surrounding skin was washed with soap and water, after which pure alcohol was freely applied. No enlarged axillary glands could be felt, especially after the growth was removed The growth weighed twelve pounds. Although a large woman, he experienced some difficulty in bringing together the edges of the flaps. Axilla was not disturbed. He had two points of suppuration, but barring this, her recovery was entirely satisfactory. It was now four and a half years since the operation, and there was no evidence *in loco* or by metastasis. The growth proved to be a spindle-celled sarcoma The essayist then reported his second case.

Dr. CUMSTON stated that every neoplasm of the breast should be removed as soon as it was palpable. The limit of three years for malignant disease of the breast as a sign that it would not recur was erroneous. He cited a case in point. He called attention to chronic interstitial mastitis, saying that this affection was more frequent in unmarried than in married women. Its pathology was not clear.

Dr. CARSTENS urged the early removal of any kind of tumor of the mammary gland. He narrated cases in which apparently benign tumors had undergone pathological changes and had developed into sarcomata.

Dr. HUMISTON held that a great many myomata of the uterus took on sarcomatous degeneration when it was least expected, and detailed an illustrative case.

Dr. THOMAS B. EASTMAN of Indianapolis discussed two points, saying that surgeons were disposed to search for enlarged axillary glands. Recent investigations had shown that a small gland might be full of carcinoma cells, while the larger glands might be free from them Both small and large glands should be examined

Dr. JOSEPH PRICE of Philadelphia stated that for many, many years he had removed the axillary gland in cases of cancer of the breast. He saw Knowsley Thornton of London, England, do the complete operation for carcinoma of the breast long before it was done at the Johns Hopkins Hospital, and that Thornton stated at that time it was invariably his rule in removing tumors of the breast to clean out the axilla, no matter what the suspicion might be.

Dr. JOHN C. SEXTON of Rushville, Ind., was constrained to believe that sarcoma of the breast was not very rare. He had seen two cases, in one of which there was a rapid recurrence, with metastasis of the ovary of the same side. This was a round-celled sarcoma, which was confirmed by an eminent pathologist. The other case was one of ordinary spindle-celled sarcoma in which recurrence took place promptly.

Dr. MILES F. PORTER desired to place himself on record as saying that every tumor of the breast was suspicious, and required operation, and in his judgment any operation which stopped short of complete removal of the breast and cleaning out the axillary gland was not good surgery, and that time would prove it.

Dr. HUMISTON said the statement made by the last speaker was too radical. Small benign tumors of the breast in young women could be readily removed by cocainization. Sections could be submitted to a microscopist, and if the tumor was found to be malignant, a complete operation should be made.

Dr. CUMSTON believed that chronic interstitial mastitis in the majority of cases was the starting point of malignant neoplasms of the breast He urged early radical and complete operation.

Dr. E. GUSTAV ZINKE of Cincinnati said it was very difficult to say before a tumor was in one's hands or under the microscope what was the actual nature of it. The physician, therefore, was placed in a very embarrassing position. He illustrated this point by narrating an interesting case.

Dr. BALDWIN asked whether it was proper to speak of cases as recurrences in which secondary growths occurred many years afterward; also, whether it was proper to speak of growths occurring elsewhere in the body as metastases. He mentioned a case in which he removed a sarcoma of the ovary with a long pedicle, but there were no adhesions. A few years afterward the woman developed a sarcoma of the kidney. He did not consider this a metastasis, nor a recurrence, but a brand-new sarcoma of the kidney. He narrated other cases.

Dr. CARSTENS made an eloquent plea against the removal of the breast in cases of small benign tumors in young girls of eighteen or twenty. He vigorously contended that it was bad practice to do it, as it blighted their prospects for matrimony, and it was absolutely unnecessary.

Dr. Ricketts, in closing, endorsed the position taken by Dr. Carstens. In his case, if he had the operation to do over again, he should have removed only the tumor, and not a part of the breast with it.

Galvanism as a Remedy for Uterine Hemorrhage.—Dr. EDWIN WALKER of Evansville, Ind., read this paper. He stated that galvanism as a remedy in gynecology had been both unduly lauded and condemned. Apostoli's method commanded the respect of surgeons, but the results had not been commensurate with claims, and had not been without danger. The minor uses of electricity partook of the character of tinkering, and were objectionable. There still remained a limited field in therapeutics for it, but it did not replace surgery. Its use in uterine hemorrhage was quite satisfactory. It should not be used where the cause of the hemorrhage could be removed by a clean surgical operation. In mild cases, in which the hemorrhage was practically the only symptom, and where no radical operation would be entertained, galvanism was the remedy. In another large class of cases, where grave disease in other organs contraindicated operation, relief and often a systematic cure could be effected. Accurate diagnosis of all lesions in each patient was of the highest importance, so that life was not hazarded by an operation in the presence of a serious lesion elsewhere which was overlooked, or the patient, even if she recovered, was not benefited for the same reason. The method of application was quite simple The positive pole is attached to a platinum electrode and introduced into the uterus; the negative pole, attached to a copper plate covered with moist absorbent gauze, is placed over the abdomen. The current is gradually turned on until a distinct burning is felt under the negative pole, and continued ten to thirty minutes. Strict asepsis is necessary. The application is not painful. Two to eight applications are required.

Dr. C. C. FREDERICK of Buffalo stated that electricity had to a certain extent been replaced largely by surgical procedures. In the experimental stages the results that had been promised by the use of electricity by a great many who were enthusiasts were not borne out. Practitioners met with poor success with it, and in consequence became disgusted, and abandoned it, and were now depending upon massage and surgical procedures to control uterine hemorrhages.

Dr. HAYD had used electricity for many years, in fact, for five months he had worked with Apostoli, conse-

quently he spoke advisedly. When he considered the amount of good that had been done with it in treating pelvic troubles, and compared it with the amount of harm wrought, he felt that it would have been the best thing if practitioners of medicine knew nothing about intra-uterine galvanization.

Dr. Price expressed the belief that the application of electricity had a great deal to do in favoring the growth and development of fibroids rather than preventing or arresting them. He detailed two or three such cases.

Dr. Carstens referred to the various causes of uterine hemorrhage. In all cases of excessive hemorrhage there was some cause for it. Sometimes the cause was constitutional and required simply constitutional treatment, but no operation. In other cases, the hemorrhage was indicative of malignant disease of the uterus. If the use of electricity was advocated in these cases, and the information was circulated among general practitioners that this agent was good for uterine hemorrhage, the result would be that a great many cases of beginning cancer of the uterus would be treated for weeks and months, and the golden opportunity to remove the disease by early and timely surgical measures would have passed, and a diagnosis would finally be made too late. He argued against the indiscriminate use of electricity for uterine hemorrhages.

Retrodisplacements of the Uterus in Young Girls and Unmarried Women; Their Frequency and Best Methods of Treatment.—Dr. Herman E. Hayd of Buffalo read a paper with this title, in which the author drew the following deductions: 1. A plea for the more careful examination of young women by competent and skilled men who can undertake any operative measures that are necessary. 2. Every case of retrodisplaced uterus in the young or unmarried or married woman may not require any treatment. 3. If they produce a definite symptomatology, the Alexander operation should be employed, if the case be an operable one, that is, if the uterus is freely movable and the tubes and ovaries are healthy. 4. Retroversions and retroflexions in the young and unmarried should never be treated by pessaries, but by the Alexander operation. Tampons and pessaries have their place in retrodisplacements in married women, or women who have been pregnant, but they accomplish practically nothing in the displacements of young women. 5. The Alexander operation is safe and without mortality incident to the operation, and no harm can come from its proper performance; even if the uterus subsequently falls, the patient is no worse off than she was previous to the operation. 6. It does not in any way interfere with pregnancy and future child-bearing, but, on the contrary, materially helps the possibility of pregnancy. 7. No pain or distress follows the operation if the case operated upon be properly selected, and if pain and suffering result, there existed at the time of the operation latent tubal and ovarian trouble, which sooner or later perhaps would have required a radical operation. If it becomes necessary to do a cœliotomy on a person who previously had an Alexander operation, the uterus will be found in its normal anteflected position, which is necessary in every case, whether the tubes and ovaries are removed or not, to insure good health and freedom from future suffering.

A Method for Suspension of the Uterus. Dr. Robert T. Morris of New York described this method. The abdomen is opened in the middle line. An incision two inches long will suffice for most cases. The peritoneum over one round ligament is split, and the round ligament is drawn out with a hook for a distance of three inches, more or less. Drawing out the round ligament with a hook makes, naturally, a long loop. The arms of the loop are sutured together with silk or chromic catgut. This throws the sutured part of the round ligament out of commission, and leaves the ligament three inches shorter, more or less. The sutured loop is tucked back into the slit in the peritoneum of the broad ligament, and the opening is closed. The operation shortens the round ligaments, and allows the uterus to ride easily and elastically in a normal position. Its advantage over other ligament-shortening operations lies in the securing of union of muscular structures. The surgeon does not have to depend upon peritoneal adhesion, which must be a failure in many cases.

Diseases and Injuries of the Cervix Uteri, and Their Treatment.—Dr. J. W. Hyde of Brooklyn, N. Y., presented this paper. The salient points in this paper are epitomized in the following conclusions: 1. In cases in which the injury is recent, and the constitution of the patient is so good that no extensive degenerations have occurred—in short, where there is a reasonable probability of being able to restore the cervix to a normal condition, this should be done by Emmet's operation. 2. In old cases, where extensive alterations have taken place, as proved by direct examination, and not less certainly by the unmistakable and intractable reflexes that attend such alterations, the unbearable headaches usually referred to the vertex and the nuchal region, the gastric disturbances, and the endless procession of psychic, neurotic, motor, cardiac, and respiratory aberrations, so familiar to every experienced physician, in such cases trachelorrhaphy is out of the question. To remove all the diseased tissue, and that alone, would call for an unattainable amount of nicety of dissection; and supposing the dissection accomplished, the sewing up of what was left might result in a most interesting thing "of shreds and patches," but it would not be a cervix uteri, which is the only legitimate object of trachelorrhaphy. In such cases, amputation is as effective clinically as it is logical in theory. 3. The operation is not more dangerous than trachelorrhaphy. 4. It is not likely to be followed by stenosis of the canal. 5. There is nothing in the operation that seriously militates against conception, or a normal gestation and delivery.

The Mechanical or Combined Plastic and Mechanical Treatment of Retrodeviations of the Womb.—Dr. M. Rosenwasser of Cleveland, Ohio, stated that retrodeviations of the womb were either simple or complicated. The complicated were subdivided into those with movable and those with fixed womb. Of 116 patients treated for retroversion, sixty-three of the second and third degrees were selected as proper subjects for mechanical treatment. They were treated by means of the pessary alone, or the plastic operation was supplemented by a pessary. From a table furnishing the details the following summary is obtained: Cured, eleven; symptomatically cured, fifteen; improved, twenty-six; not improved, eleven. In the body of the paper the writer considered each of the divisions, as above classified, and illustrated each by a brief history of typical cases. He maintained that cases of complicated retroversion with movable uterus could be converted into simple ones by plastic operations, and were then subject to treatment by mechanical support. After refuting the objections generally raised against the pessary, he submitted the following conclusions, based upon the present imperfect status of suspension operations: 1. A retroverted womb uncomplicated by disease should be replaced and supported by a pessary. 2. Retroversion complicated by diseased womb, or by impaired pelvic floor, the womb being movable, requires preliminary plastic operation to restore the normal condition before using a mechanical support. 3. Suspension operations should not be done simultaneously with the plastic in face of a probability that a pessary can sustain the uterus in position. 4. Retroversion complicated by aggravated prolapsus requires simultaneous plastic and suspension operations to effect a cure. 5. The treatment of retroversion with fixed womb is that for pelvic inflammation. Whenever the latter requires laparotomy, or colpotomy, the retroversion becomes subject to such surgical treatment as may appear best suited to the particular case.

o Retroversion simple or complicated in which mechanical support and plastic operation have failed to cure or to relieve, and in which the symptoms demand relief constitutes a proper indication for a suspension operati n

Second Day—Wednesday, September [illegible], 1901.

Some Observations on the Surgery of the Spleen. Dr Lewis S. McMurtry of Louisville presented this paper Knowledge of the physiology and pathology of the spleen is so imperfect that the surgery of this organ has not advanced proportionately with that of the other organs of the abdominal cavity. In view of this fact, every case which may possibly contribute to our knowledge should be studied and recorded. He then reported a case of large cyst of the spleen. The patient was a vigorous woman of thirty, well nourished, with a fluctuating abdominal tumor, appearing upon the left side of the abdomen, and readily movable from pelvis to diaphragm. The diagnosis was ovarian cyst with elongated pedicle, or floating cystic kidney. On abdominal section, the tumor was found to be a cystic spleen. This was removed without difficulty and without hemorrhage, followed by prompt recovery. A careful microscopic examination showed the cyst to be simple and sterile. Three similar cases were reported

The essayist then considered the technique of splenectomy for cystic tumors of the spleen, commending the median incision and enucleation from below. He stated that it was not the purpose of the paper to consider all varieties of diseases of the spleen, nor to tabulate the statistics of splenectomy for hypertrophy and miscellaneous diseases, but rather to show that cystic degeneration of the spleen is sufficiently common to make a class of tumors deserving recognition as a factor in the diagnosis of cystic tumors of the abdomen. The results of operation in these cases show that the spleen is not essential to life and health

Is Cæsarian Section Justifiable in Placenta Prævia? — Dr. E. Gustav Zinke of Cincinnati went rather exhaustively into the history and literature of this subject, and considered the cases reported. He referred to the justifiability of the operation, and the class of cases to which it is applicable. He likewise dwelt on the contraindications to the operation, and compared the management of placenta prævia with and without cæsarian section. He believed that the cæsarian and the Porro operations were perfectly legitimate and elective procedures in all cases of placenta prævia, central and complete, and especially so when the patient was a primipara, when the os was closed and the cervix unabridged; when hemorrhage was profuse and could not be controlled by tamponade and separation of the placenta around the internal os. That there were cases of partial prævia that might be successfully treated in the old way, he did not doubt. Perhaps a small majority of all the placenta-prævia cases could be treated successfully, so far as the mothers were concerned, after the manner of Fry and De Lee. But what of the large minority of mothers that succumb, and the great majority of children that are sacrificed at once? The question presented was a very serious one, and should be earnestly considered, and when confronted with a case of central or complete placenta prævia, or any other variety, where dilatation of the cervix was impossible or difficult, the patient and her immediate friends should be made acquainted with all the facts concerning both methods of treatment. If properly presented, he thought it was doubtful whether the majority of women would select forcible dilatation, version, extraction, etc. Personally, he would retire from a case were cæsarian section refused, if recommended as the safest procedure, and this in spite of adverse criticism.

President's Address.—This was delivered by Dr W. E. B. Davis of Birmingham, Ala. After congratulating the association upon the great work it had accomplished, he urged the Fellows to use their influence in the better organization of the sections of the American Medical Association, which he said ought to be the greatest and most influential medical organization in the United States. He then took up a consideration of the principal operative procedures for cholelithiasis. He favored cholecystotomy, as a rule, in cases of gall-bladder and cystic duct calculi. He said that much has been claimed within the past five years for cholecystolysis, with or without drainage of the abdominal cavity. While this operation has something to commend it, being simple and obviating the disagreeable discharge of bile, for a period of from three to four weeks from a fistula, yet its field is limited when the etiology and pathology of cholelithiasis are given due consideration. Stagnation of bile with altered epithelium and infection from the typhoid or colon bacillus, as found in many cases, where there is no evidence of infection from the character of the fluid in the bladder, would contraindicate its closure. If stones should be found, where an examination of the gall-bladder is conducted through the abdominal incision made for the relief of pelvic disease or other abdominal trouble, cholecystendysis might be performed with advantage. He advised strongly against the operation as performed by Kelly. The primary incision in the abdomen should be closed, and the opening made as in the classical cystotomy. Cases in which calculi would be found by this method are not associated with inflammatory changes, and are the ones who go through life without symptoms referable to the gall-bladder being found at the autopsy or in the dissecting room. The operation of cholecystostomy, he said, should be reserved for stricture of the cystic duct inflammatory changes which greatly endanger the walls of the bladder, and malignant disease.

In discussing stone in the common duct, he said that choledochostomy without suture is called for in the large majority of common-duct stones. Suture of the duct may be practised if the patient's condition has not been rendered serious by much suffering and protracted jaundice, and if the duct is enlarged and not markedly inflamed. Gauze drainage should be resorted to in all cases, it matters not how carefully the stitching of the duct has been carried out. The time required for suturing the duct adds very greatly to the gravity of the operation, in cholemia of long duration. It would also be contrary to surgical practice elsewhere to suture when offensive infected bile escapes from the duct. Morrison's pouch, which will hold nearly a pint of fluid, makes drainage in this location entirely satisfactory. The lumbar stab is preferred by some surgeons, but the entire safety of transperitoneal drainage has been abundantly demonstrated. Kehr, who has done more gallstone operations than any other surgeon, claims that he first advised the open treatment of the duct; but it is known that he is in error, as the operation has been urged for the reasons he gives, in this country, since the early part of 1892, at which time experiments were conducted by me on lower animals and reported to the American Medical Association. At that time, and for some years afterward, it was admitted by surgeons that the operation would succeed on normal organs with normal bile, but not otherwise. I afterward induced pathological changes in the biliary passages, and demonstrated that the operation was successful in infected and enlarged ducts. Experimental and clinical experience demonstrates conclusively the safety of the operation.

At the Indianapolis meeting, two years ago, Dr. Davis reported two cases in which hepatotomy had been done in obstruction to the biliary passages. The operation is indicated in cases of obstruction with enlarged liver where the gall bladder or duct cannot be isolated, if the patient's condition from exhaustion and cholemia will not permit of a protracted search for the bladder or ducts. After the patient's condition is better, a rapid operation may be done. It will only exceptionally be called for, and the cases will be fewer as the surgeon's experience in-

creases in choledochous operations; for he will then be enabled better to locate the bladder and ducts so much changed by inflammatory processes. In addition to the above-mentioned indications, he thought the operation should be resorted to in hepatitis before it has reached the stage of pus-formation, if the liver does not rapidly become smaller after drainage of the biliary reservoir of the duct. His attention was first attracted to the value of the procedure in a case in which the amount of pus removed was not more than half an ounce, but in which the division of the biliary canals resulted in the escape of large quantities of bile for many weeks. In December, 1898, he had done hepatotomy on one case in which there was a movable stone in the common duct, and, in the same month, in a case of obstruction of the hepatic ducts by malignant disease.

In July and August of this year he had conducted a number of experiments on dogs to determine the value of incisions in the liver in relieving biliary obstruction. Five dogs were killed and the liver injected with fluid, either through the gall-bladder, the common duct having been tied, or through the common duct. Incisions were then made in all parts of the liver, with the result that streams of the fluid would issue from the bile canals and general oozing of the fluid from the wounded surfaces of the organ if much force was used. Six were anæsthetized and the liver injected as above, and this fluid with blood would flow, as a rule, freely when much force was used in injecting the fluid. Four had the common duct tied, and after twenty-four hours the same experiment was conducted under anæsthesia, with similar results. In nine, the common duct was ligated and gauze packed around the field of the gall-bladder and ducts. After from twenty-four hours to a week the liver would be incised in one or more places, and, as a rule, the bile escaped satisfactorily through the gauze. It would be very dark after prolonged obstruction. Two of the dogs died, and the others were killed in from five days to two weeks. Before killing them, and while under the anæsthetic, fluid was injected through bladder or duct, and would flow from the wounds which had been previously made in the liver and also from incisions made at that time. Five had the gall-bladder removed and the cystic and common ducts ligated, but as gauze was not used at the time of operation to wall off the general cavity, they died in from twenty-four to forty-eight hours from the escape of bile, with shock.

With the advance in surgery of the choledochus, the field for cholecystenterostomy grows smaller. Dr. Davis said that he was assisted in his experimental work by Dr. R. E. Hogan of Birmingham.

Second Day—Afternoon Session.

Gallstone in the Common Duct; Its Frequency, Symptoms, Diagnosis, and Treatment.—Dr. L. H. Dunning of Indianapolis quoted from the recent paper of Mosher, whose compilation of the Johns Hopkins Hospital Records shows that gallstones are present in 0.04 per cent. of our population, and that in 13 per cent. of all cases of gall stones the calculus is arrested in the common duct. For convenience of description, the author adopted the generally accepted classification of gallstone in the common duct, namely: (1) the acute form in which there is acute obstruction, transient jaundice, and the typical gallstone colic, (2) chronic obstruction of the common duct from lodgment of a stone somewhere in the course of the duct. The first division represents the old classical form of bilious colic, and the symptoms are so well known that he did not enumerate them in detail. In chronic obstruction from gallstones the jaundice is more or less intermittent and there is pain in the hypochondrium, epigastrium, and back. The pain is not so severe as in acute obstruction, and is very irregular. It may be located in the epigastric or lumbar region. As a rule, there is absence of a tumor in the gall-bladder region, but marked soreness. There is marked loss of weight and frequently chills and intermittent fever.

The Carlsbad cure, a sojourn at the French Lick Springs, large draughts of oil, the application of hot fomentations to the hypochondrium, and opiates to relieve pain, are all of benefit in the acute cases. The chronic cases are amenable to surgical treatment alone. The author cited and remarked upon the various methods of surgical procedure. Choledochotomy was shown to be the most approved method when applicable. The middle third of the duct is the point of choice for the incision. When the stone is in the duodenal end of the duct, it can usually be crowded back into the middle portion and removed through an incision in that part. An incision through the cystic duct may be carried onward into and through the common duct, if the upper portion be chosen for the line of incision. Duodeno-choledochotomy is applicable to cases of a large fixed stone in the duodenal extremity of the duct. This method yields a higher rate of mortality than simple incision of the choledochus. Only soft stones should be crushed, and needling is unsatisfactory. The writer would reserve cholecystenterostomy in common duct obstruction for those cases in which the patients could not endure the longer operation of choledochotomy. Four cases were reported in detail.

Dr. George S. Peck of Youngstown, Ohio, reported some cases of extra-uterine pregnancy, and presented specimens.

Dr. M. Rosenwasser detailed a case of tubal pregnancy upon which he operated in the eighth week, immediately before the occurrence of rupture.

Acute Pancreatitis and Fat Necrosis.—Dr. Edward J. Ill of Newark, N. J., reported this case, because of the rarity of the disease and the interest attached to the operations for this ailment. The patient was a woman, forty-three years of age, with the usual history of gallstone colic. She was taken sick suddenly with excruciating pain in the epigastrium, excessive vomiting, and obstruction of the bowel. In twelve days after the onset of the disease a tumor was made out. The patient was operated on the twentieth day after the onset of the disease. The diagnosis was perforative inflammation of the gall-bladder, although a pancreatitis with fat necrosis was suggested. The patient's urine contained bile, albumin, and granular casts, with a specific gravity of 1.028. It contained no sugar. The operation consisted of a right lateral abdominal section, and an opening between the stomach and the transverse colon through an immensely thickened omentum. Fluid was reached at the head of the pancreas, which was drained through a rubber tube and iodoform gauze. The whole pancreas seemed to be involved in the disease. The omentum, upon section, showed whitish gray nodules, containing brown roundish spots. A second operation was done for her relief. For a time the patient seemed to do well, but in about seven weeks she had a relapse, from which she died in three weeks. At the post mortem it was shown that there were four gallstones in the gall-bladder and only a small mass of gristly substance of the pancreas was left.

Dr. Ill likewise reported and showed specimens of an interesting case of papilloma of the vulva.

Early Operations in Appendicitis and Method was the title of a paper by Dr. Joseph Price of Philadelphia. In the last three months he had operated on about one hundred cases of this disease. Seventy-five per cent. had been managed by open treatment. All of them had been explosive cases, and none of the operations was done the first or second day. In two, ball players, the operations were done on the third day. In both cases he found gangrenous appendicitis with perforations, and general peritonitis. Both were recognized and could have been operated on twenty-four hours earlier. He was satisfied that there was but one treatment for this disease—early clean removal of the appendix. The choice of method should not worry operators. A pair of scissors with

needles and fine thread was all that was necessary. The appendix should be cut off smooth with the cæcum, and the opening closed with fine silk. This summer the operations had been done by him chiefly on children between the ages of eight and twenty. About 75 per cent. were boys—fine, athletic chaps, and about 25 per cent. girls. A large number of the latter were menstruating at the time of the operation. In some instances it complicated the diagnosis. The disease had been quite common and fatal at summer resorts. A large number of operations had been done at Atlantic City, and a few patients were sent home for operations. The interval operation had done much to mislead the general practitioner, and much to complicate operation, in which there should be no complications.

Third Day—Thursday, September 19.

Vaginal Hysterectomy with Four and a Half Months' Pregnancy and Closed Cervix.—Dr. J. HENRY CARSTENS of Detroit reported this case. The patient was a woman, Mrs. D., only twenty-six years of age, mother of three children. She was afflicted with some inflammation and ulceration of the womb. Finally a diagnosis of cauliflower growth was made by a practitioner. The cervix was removed in February, 1900. She recovered and improved very much in health; menstruation continued regularly, but during the summer, about six months later, she again had trouble. On examination a recurrent growth was found. This was treated by curetting and strong cauterization, the latter being continuously and vigorously applied. Examination revealed a large uterus, such as is found in cases of pregnancy at four and a half months, well-marked placental bruit, enlargement of the breasts, etc. The upper end of the vagina was absolutely closed by a cicatrix, as is found after vaginal hysterectomy. There were two nodules, the size of a hazelnut and a bean. By allowing the pregnancy to continue, the malignant growth would probably have closed up the vagina and a cæsarian section would have been necessary, and the cancer would have so far advanced that there would have been little chance for permanent recovery. Hence a prompt operation seemed necessary, but how? If there had been an opening he would have had the physicians insert a catheter and bring on premature labor a week before, and then remove the uterus. Having the patient under chloroform, he plunged a pair of scissors into the place where he thought the os ought to be. By separating them and stretching the opening with his finger, he tore the sac. By enlarging the opening he had no further trouble in delivering the fœtus. By pressing the womb the placenta was soon delivered, although the hemorrhage was profuse for a few minutes, but the uterus contracted firmly, and there was no further trouble. In tearing the opening he fortunately ruptured into the cul de sac. This served as a guide for him to work, and although the uterus was very large, he finished the operation and did a vaginal hysterectomy. Patient recovered and is well to-day.

Indications, Technique, and Remote Results of Salpingostomy and of Resection and Ignipuncture of the Ovaries.—Dr. A. GOLDSPOHN of Chicago read a paper on this subject and presented tables of 104 cases. The conclusions of the author were as follows: 1. In patients who are not near the menopause, and who are not tainted by tubercular or malignant disease, one or a part of one or both ovaries can frequently be preserved, with or without the retention of the corresponding tube, in the following conditions: (*a*) In follicular cystic degeneration or partially cirrhotic induration due to inflammatory processes or other circulatory disorders; (*b*) in extirpating parovarian cysts, dermoid and fibroid tumors with or without the uterus; (*c*) with great caution, in the extirpation of non-papillary glandular cystomata, that are devoid of surface papillomata and other evidences of malignancy. 2. Necessary for success in the resection of the uterine adnexa is the exercise of asepsis of the highest degree, and the use of a minimum amount of fine and readily absorbable suture material, exclusively and judiciously, as to tension. 3. A generous median ventral incision provides the best access for the conservative treatment of the adnexa in cases where septic accumulations in the parts are not absent, and when extreme fixations of the parts abound. When these more extreme complications are not present, and a retroversion of the uterus exists, the resection of the adnexa is most easily effected by way of the dilated internal inguinal rings in conjunction with a thorough Alexander operation. 4. Vaginal cœliotomy does not provide a favorable access for conservative surgical treatment of ovaries and tubes. It does frequently admit of ignipuncture, but is not auspicious for resection of ovaries. 5. Resection, with the care and technique alluded to, is the more ideal and most conservative measure, and should be preferred when the parts are sufficiently accessible without undue traction upon their lateral supports, and when asepsis in the surrounding wound and in the general execution is reasonably assured, otherwise thermo-cauterization is probably better.

Dr. C. C. FREDERICK of Buffalo, N. Y., read a paper in which he narrated some very rare and old cases and experiences in pelvic and abdominal surgery, and the lessons they taught him.

Dr. CHARLES GREENE CUMSTON of Boston reported two cases of hour-glass stomach, and discussed the pathology and treatment.

Personal Experience with Uterine Fibromyomata.—Dr. HENRY D. INGRAHAM of Buffalo mentioned a large number of cases of uterine fibroids which he had treated by various methods during the past sixteen years. Although he had used ergot freely in many cases, it was only in a very few that it had any effect on the hemorrhage, and possibly hydrastis had in some cases. Stypticin had, in his experience, appeared to check the excessive flow better than any other drug. He had not obtained any special benefit from the use of the thyroid extract or desiccated mammary gland, and considered their use dangerous on account of their effects upon the general health of patients. He had formerly used electricity with benefit, but did not use it now, as the results were not satisfactory. He had had seven cases of quite large fibroids complicated with pregnancy. In five miscarriage occurred spontaneously. In one it was induced, and in the other the growth almost completely filled the pelvic cavity, the four and one-half months' fœtus being above it, so that a hysterectomy was necessary. The patient recovered. One case was mentioned of an unmarried woman who was sixty-four years of age before the fibroid began to show signs of its existence. For some time it was dense and hard, and grew slowly, but for the past few months it had become cystic, and increased in size rapidly. This patient manifested several cerebral symptoms on three different occasions, which the author believed were due to some particles of the disintegrating tumor becoming detached, and were carried to the brain, producing these symptoms. On one occasion patient lost sense of motion and sensibility of the right side for over two weeks, and did not know the members of her own family for the same length of time. During the height of this attack the temperature was 101° F., and pulse 96. A year later she had a similar attack, and a few months ago another one, but milder, with no rise of pulse or temperature. He believed that fibromyomata, although considered benign in contradistinction to malignant growths, were by no means harmless, but exposed the patient to great and increasing risk. All cases of fibroids should be carefully watched. If they were not giving any trouble or increasing in size, they should be let alone, but the patient should be kept under observation. When they gave rise to trouble, or if the growth increased in size, then the proper thing to do was to remove it before dangerous complications occurred. If there were adhesions or necrosis of the tumor or pyosalpinx, then the danger of the operation was

greatly increased. If cardiac disease or hydrothorax resulted as a complication, the removal of the tumor would not relieve those conditions. Waiting for the menopause to relieve the diseased condition was often like holding out false hopes to the patient, as the trouble might become worse then than before, or it might all develop after that period, as was shown by the recital of the last case reported by the author. If any treatment was necessary and the patient was in a suitable condition, a radical operation should be done. There was no excuse in his opinion whatever for palliative or temporizing treatment at the present day.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. Edwin Ricketts of Cincinnati; *Vice-Presidents*, Drs. Charles Greene Cumston of Boston and Miles F. Porter of Fort Wayne, Ind.; *Secretary*, Dr. William Warren Potter of Buffalo; *Treasurer*, Dr. X. O. Werder of Pittsburg, Pa. Washington, D. C., was selected as the place for holding the next annual meeting, in 1902.

Medical Items.

Reduction of the Body Temperature by Mechanical Means.—Erm has found that by tapping the chests of consumptives with a silver paper-cutter, it is possible to cause a reduction of temperature of from 0.2 to 0.5° C. This effect makes itself manifest immediately after the treatment, and persists for some time; under daily repetition of the measure, the fever is said to be brought down to the normal. The amount of expectoration is at the same time greatly increased, which perhaps accounts for the lessened temperature observed in the long run. Sahli criticises the author's conclusions as being based on insufficient material, and says that such variations as are recorded are too trifling to be of practical value.—*Correspondenz-Blatt für Schweizer Aerzte.*

A Practical Method for Demonstrating Tubercle Bacilli when Associated with Influenza Bacilli.—A. J. Comstock thinly spreads the suspected sputum or other containing medium on a cover glass or slide; allows it to become air dried and then flames it. Next he applies Ziehl's solution with the aid of heat, as for staining tubercle bacilli. He passes the preparation through 15 per cent. aqueous solution of nitric acid, washes in 60 per cent. alcohol, and rinses in fresh water; dries the preparation, and then applies Loeffler's alkaline-methylene-blue, aided by heat, as Ziehl's solution was previously applied. Then he washes thoroughly under a stream of fresh water. This removes most of the stain from other elements in the sputum without danger of washing the fuchsin from the tubercle bacilli, or the methylene blue from the influenza bacilli. Lastly, he dries the preparation and mounts it in balsam. The tubercle bacilli retain a brilliant red color and the influenza bacilli are stained blue.—*Southern California Practitioner.*

The Effect of the New Civil Code in Japan, as Regards Marriage and Divorce.—The following statistics on this subject are interesting from the fact of the apparent influence exerted by the new laws, recently promulgated in Japan, upon society. Tables recently compiled by the authorities show that whereas formerly there used to be eight marriages annually per 1,000 inhabitants, the number has fallen to 6.78 since the promulgation of the new Civil Code. This change for the worse is attributed to the fact that the formalities connected with marriage having become much more complicated under the new law, there is a disposition to dispense with the ceremony, especially since, in the event of the birth of a child, it can be legitimatized by subsequent marriage. On the other hand, the new law of divorce has produced a wholesome effect. Under its operation the number of divorces has fallen from 33 per 100 couples to 22.35. In other words, whereas formerly out of every three marriages one resulted in divorce, the ratio has changed to nearly one out of five.

Report of a Cyst Implanted on the Fallopian Tube, and Containing the Ova of Oxyuris Vermicularis.—Giovanni Marro, during the course of an autopsy upon an insane patient of thirty-four years, who had died of marasmus, found a cyst the size of an orange adhering to the right ovary and tube, with two smaller cysts on the left. The smaller of the two latter, about the size of a pea, situated on the fimbriated extremity of the tube, was found to contain the ova of the oxyuris vermicularis. The migratory tendency of the female oxyuris are well known; in this case it probably invaded the vagina and uterus and traveled through the Fallopian tube, becoming incapsulated, and depositing its eggs before detaching itself from the place. The ova having extremely resistant walls, would be able to live even in the midst of the exudate, and the cholesteric crystals which form the cyst contents.—*Archivio per le Scienze Mediche.*

Intestinal Hemorrhage in Pneumonia, says the *Practitioner*, is a rare event, although ulcers in the colon are sometimes seen in patients dying from pneumonia. Vialard records two cases of pneumonia presenting this complication; both the patients recovered, so no opportunity of examining the condition of the alimentary canal was forthcoming. In both cases the lower lobe of the right lung was involved. The hemorrhage was probably due to pneumococcic enteritis, set up by the action either of the toxin or of pneumococci. Cases of pneumococcic hemorrhagic ulceration of the stomach and duodenum, described by Dieulafoy and by Griffon, were referred to in the *Practitioner* for February, 1900. Vialard found that the treatment of this form of intestinal hemorrhage by perchloride of iron given by the mouth was satisfactory.

Electro-fanitis.—The great heat to which we have been subjected this summer reminds us of the assertion which appeared in an Indian medical journal last year, that a new hot-weather ailment had come into existence, called "electro-fanitis." It emanated from the United States, which is the land of the electric fan. The disease in question is a sneezing, coughing, cold in the head, caused by the germ-laden breezes of the ventilating fan. It is almost epidemic, and, unless treated, results in tonsillitis and bronchitis. Being caused by artificial atmospheric conditions, it is more difficult to cure than the ordinary cold. Furthermore, these currents of air are not the fresh waves of ozone which are in circulation out of doors, but are merely impure air forced into motion.—*Medical Times and Hospital Gazette.*

Emergency Purification of Water by the Method of Lapeyrère.—In a paper read in the subsection for Military Hygiene of the Congress of Medicine, held in Paris last year, Lapeyrère suggested a new method for the purification of water for the use of troops on active service. A powder consisting of permanganate of potassium, 3 grams; aluminate of sodium, 10 grams; carbonate of sodium, 9 grams; carbonate of calcium, 3 grams, is added to 100 liters of water. After standing for a few minutes the water is passed through a filter constructed of a drum of unoxidizable metal, packed with purified peat fiber, mixed with black oxide of manganese. This process is said to combine sterilization of the water with precipitation and clarification.—*Public Health.*

The Toxin of Tinea.—G. Messineo and D. Calamida report a series of experiments conducted with the view of ascertaining whether the injurious action of tinea is due to toxic substances elaborated by it, rather than to mechanical causes. Their conclusion is that such a toxin is produced, but whether it is a product of secretion of the tinea, or an ultimate product of nutritive interchange due to the influence of the parasite, is not yet certain.—*La Riforma Medica.*

Book Reviews.

MERCK'S 1901 ANNUAL. New York and Chicago: Merck & Co.

THIS little handbook of 280 pages, but of a size convenient for the pocket, contains the names and chief synonyms, physical appearance, solubilities, physiological effects, therapeutic uses, modes of administration and application, dosage, incompatibles, antidotes, etc., of the chemicals and drugs used in modern medical practice; a comprehensive collection of prescriptions, embracing also the newer remedies of established merit; a classification of medicaments; a brief yet comprehensive treatise on toxicology, diagnostic tables, obstetric charts, notes on pulse frequency, tables for the interconversion of the metric and English systems of weights and measures, etc.

LE DIAGNOSTIC PRÉCOCE DE LA TUBERCULOSE PULMONAIRE. Par MM. les Drs. CH. JOURDIN et G. FISCHER, Médecins Aides-Majors. Paris: A. Maloine, 1901.

THIS little work is full of valuable suggestions regarding the early diagnosis of tuberculosis. It is divided into three parts. The first includes a consideration of the symptoms which are related to the external examination of the patient, and of the lungs; the second, of those concerned with the blood and circulation and the organs of that system; the third deals with the effects on the organism of the administration of tuberculin, and with serum-reaction.

AN INTERNATIONAL SYSTEM OF ELECTRO-THERAPEUTICS. For students, general practitioners, and specialists. By numerous associated authors. Edited by HORATIO R. BIGELOW, M.D., Permanent Member of the American Medical Association; Fellow of the British Gynecological Society and of the American Electro-Therapeutic Association; Member of the Philadelphia Obstetrical Society, of the Société Française d'Electro-Thérapie, and of the Anthropological and Biological Societies of Washington, D. C.; author of "Gynecological Electro-Therapeutics" and "Familiar Talks on Electricity and Batteries." Second edition. Revised and brought up to date, with several new departments embodying the most recent developments of the science. Edited by G. BETTON MASSEY, M.D., ex-President and Fellow of the American Electro-Therapeutic Association; Member of the American Medical Association; author of "Conservative Gynecology and Electro-Therapeutics," etc. Philadelphia: F. A. Davis Company, 1901.

IN the seven years since the first edition of this valuable work was published many advances have been made in the application of electricity to the cure of disease, and in some directions favorable opinions have had to be revised, certain alleged effects of this subtle force having been shown not to exist—at least, not in the degree at one time believed. Four entirely new articles appear in this edition, namely, on the Rontgen rays, the galvanic current, the treatment of cancer by the cataphoresis of mercury, and the electrical treatment of aneurysm, written by Max J. Stern, G. Betton Massey (the author of two articles), and D. D. Stewart, respectively. The list of contributors of the thirty-eight articles contains the names of very many men in this country, England, and France who have themselves done much to raise this branch of therapeutics from the disrepute in which it was once held to a position level with that of the other departments of the art of curing disease. Those who have known the first edition of this work will welcome the appearance of a new and revised edition, edited by such a man as Dr. Massey, and those who hear of it now for the first time may be assured that, if they are interested at all in electro-therapeutics, and desire to know more of it, they cannot do better than turn to this encyclopedic treatise. As a work of reference its usefulness is enhanced by a copious index. The illustrations are many and helpful.

HANDBUCH DER PHYSIKALISCHEN THERAPIE. Unter mitwirkung von Prof. Bernhard (Berlin), R. du Bois-Raymond (Berlin), Dr. Binn (Wien), und andere, herausgegeben von Dr. A. GOLDSCHEIDER (Berlin) und Dr. PAUL JACOB (Berlin). Teil 1, Band I. Mit 69 Abbildungen. Leipzig: Georg Thieme, 1901.

THIS is the first section of what promises to be an extensive work upon its chosen subject. Climatic and atmospheric conditions naturally occupy considerable space, and the effect of varying air pressure on diseased conditions is elucidated in several chapters by different authors. Baths and hydrotherapy occupy another important section. Several valuable measures receive attention here, such as the hot pack and various forms of partial and complete bathing, with and without medicamentous additions. There is an interesting chapter on sea voyages and their effect in general, and on particular diseases which are detailed; and as an addendum, a general description of seaside resorts and their uses is given. When completed, this work will, without doubt, prove a valuable work of reference, and will perhaps be translated into English. There is a long list of collaborators, most of whom are well known in their own departments.

GOLDEN RULES OF HYGIENE. By F. J. WALDO, M.A., M.D., D.H.P., Barrister-at-Law, Medical Officer of Health, Inner and Middle Temples; Late Medical Officer of Health, St. George the Martyr, Southwark; Late Tutor in Public Health, St. Bartholomew's Hospital Medical School, etc. Bristol: John Wright & Co. London: Simpkin, Marshall, Hamilton, Kent & Co. 1901.

THIS is a "vest-pocket" book of seventy pages, in which the author has endeavored "to present the reader with a few salient points that may prove of service to him in acquiring a practical knowledge" of hygiene. The subjects treated of are air, water, disposal of refuse, food and infectious diseases.

SURGICAL DISEASES OF THE KIDNEY AND URETER. Including Injuries, Malformations, and Misplacements. By HENRY MORRIS, M.A., M.B. (Lond.), F.R.C.S., Vice-President and Chairman of the Court of Examiners, Royal College of Surgeons, Senior Surgeon Middlesex Hospital, etc., etc. With two colored plates and upward of 200 engravings. In two volumes. Vol. I and II. London, Paris, New York, and Melbourne: Cassell & Company, Ltd., 1901.

IN the two handsome volumes before us, we have the work of a writer who is one of the best-known authorities in the world on the diseases of which he treats, and we can, therefore, look upon the present work as of great value and importance. The author previously published several books upon cognate subjects, and the present volumes may be considered an amplification and continuation of these. The volumes may be considered together, and here we might insert a word of satisfaction that there are two volumes, and not one so cumbersome as to be a burden to hold. The anatomy and relations of the kidneys and ureters occupy the first chapter, which is short and concise. Chapter II is taken up with abnormalities of the kidney, which have always been of interest to the anatomist and surgeon. A number of interesting illustrations are given, and the chapter contains some useful statistical information on the occurrence of deformities and displacements. The author has had a large experience with movable or floating kidney, and he does not place much reliance upon belts or other mechanical appliances, on account of several drawbacks and dangers connected with their use, but he does believe in operative intervention, the methods of which he details. Injuries to the kidneys occupy several chapters containing much of interest. The author has made free use of clinical descriptions and references, many of the latter of historical interest. Many of the clinical references are from American sources, the American Rebellion contributing a great number of cases, especially of gunshot injuries. The extravasation of blood and the collection of pus around a kidney are important conditions, and the latter common enough under the name of perinephric abscess. Morris gives us an excellent clinical picture of the disease, and its differential diagnosis. The treatment is so obvious as hardly to need comment. Hydronephrosis is illustrated with a number of very characteristic instances of the disease. New growths of the kidney are interesting even if not very common, and in these volumes they receive perhaps less than their proportionate share of attention; renal tuberculosis, however, is fully presented. Nephrectomy is the only real treatment. A large part of the second volume is devoted to calculous disease, on which the author's opinions are known to be of value. Many different forms of calculi are described and the symptomatology of the disease searchingly gone into; after this every form of treatment is taken up and analyzed, with the result that we may consider this portion of the work definitive on the subject. A considerable mass of clinical and statistical detail is introduced. The surgery of the ureter has only in the last few years been extensively developed, but much has been written in that period, especially on methods of repair after accidental or intentional wounds. Calculous obstruction naturally receives the greatest amount of space. The author states that nephrectomy is the last resort in cases of ureteral fistula. Detailed instructions are given as to the performance of the different ureteral operations, and illustrations are frequent enough to make matters clear. The volumes are carefully indexed and handsomely made, and form a valuable addition to modern surgical literature.

PANHYSTEROKOLPECTOMY: A NEW PROLAPSUS OPERATION.*

BY GEORGE M. EDEBOHLS, A.M., M.D.,
NEW YORK.

THE essentials of the new prolapsus operation which I have the honor to present for your criticism and discussion consist, as indicated by the title, in complete extirpation of the uterus and vagina, followed by operative obliteration or columnization of the bed of the genital tract, all performed at one sitting. The effect of the operative obliteration or columnization of the bed of the removed uterus and vagina, performed in the manner presently to be described, is to build a solid pelvic floor ten to fifteen centimeters in depth from peritoneum to perineum, and to establish broad apposition of the base of the bladder and the anterior surface of the rectum, conditions similar to those obtaining in the male pelvis. A relapse or recurrence of the prolapse, after a successfully performed operation of this character, becomes a physical impossibility.

In selecting a name for the operation I have decided in favor of panhysterokolpectomy, as indicating the essentials of complete removal of the uterus and vagina. Pankolpohysterectomy, or kolpohysterectomy, would answer equally well, but the latter term has come into such common acceptation to designate removal of the uterus by the vaginal route, that its use in connection with the operation proposed in this paper would tend to unnecessary confusion. Aidoiectomy (*αἰδοια*, the genitals) presented itself, but was rejected because the vulva, a part of the genitals, is never removed, and ablation of the tubes and ovaries may be practised or omitted, according to circumstances, in the performance of the operation. Of the four patients I have operated upon, two retain both uterine adnexa and one the right ovary; in the fourth both adnexa were removed in one piece with uterus and vagina.

The statement is probably within bounds that no operator of larger and longer experience is entirely and absolutely satisfied with the results of all of his operations for complete prolapsus of the uterus and vagina. The very multiplicity of prolapsus operations, and the various combinations thereof, would indicate the truth of this assertion, and it may without reservation be admitted that there are cases of complete prolapsus in which the tissues upon which we must depend for support after operation are so relaxed that none of the operative procedures heretofore in vogue, nor any combination of them, will insure against a redescent of the uterus and vagina, or of the vaginal walls when the uterus has been removed. It was an experience with just such a case as this, Case I, in which various procedures at my hands, removal of the uterus and ventral suspension of the vagina included, had failed to secure permanent relief, that led to the development of the new operation. Fuller details of this somewhat remarkable case will be found in the appended history. Case IV, also, had been operated upon twice previously by two operators of acknowledged skill and experience, with return of the prolapsus soon after each operation.

My operation, properly and successfully performed, guarantees a certain and permanent cure of every case of prolapsus of the uterus and vagina. The more complete the prolapsus and the more unfavorable, therefore, the chances of permanent cure by other operative procedures, the more pronounced is the indication for the new operation, and the greater the facility attending its performance.

The operation is indicated whenever the certain and permanent cure of a prolapsus of the uterus and vagina, either primarily or after the failure of previous operation or operations, forms the one paramount desideratum, other considerations in comparison being relegated to the background. The limitations of its applicability and the contraindications arise from the necessity or desirability, in any given case, of perpetuating the functions of the uterus or vagina. In women past the child-bearing age the uterus need, of course, not be considered. It is quite a different matter, however, with the vagina, and the impossibility of further sexual relations must be clearly presented to the patient, and fully understood and accepted by her prior to deciding upon the operation. If the patient be a widow past the menopause, the decision will rest entirely with her; if a married woman, her husband must be consulted as well. My first case was a married woman of thirty-six in whom repeated previous operations had failed to give permanent relief. Her condition was so distressing that both she and her husband willingly sacrificed their conjugal pleasures on the altar of the wife's health. The second and third patients were widows, aged sixty-eight and fifty-one respectively, both of whom had no other desire than to be relieved of their troublesome complete prolapsus. The fourth patient, a married woman of sixty-seven, in view of two unsuccessful previous operations, had no hesitancy in accepting an operation which promised a permanent cure, though involving the loss of the vagina.

The operation is inapplicable, therefore, during the child-bearing period of life, whenever further offspring is both possible and desired at whatever hazard as regards the permanent cure of the prolapse. It is contraindicated after the child-bearing age whenever the further use of the vagina is desired by the patient or her husband. Under both the above conditions the combination of curettage, amputation of cervix, anterior colporrhaphy, and colpoperineorrhaphy, or bilateral colporrhaphy, and ventral fixation of the uterus, all performed at one sitting, as first practised by the writer in 1891 (*American Journal of Obstetrics*, 1893, XXVIII, No. 1, Case V), will probably best meet the indications.

I have once, however, partially applied the prin-

*Read before the American Gynecological Society, Chicago, May 30, 1901.

ciples underlying the new operation in the case of a married woman, aged fifty-one, suffering from multiple fibromata of the uterus associated with complete prolapsus, of which she wished to be relieved without losing the power of copulation. In this instance I removed the uterus and the upper ten centimeters of the vagina, obliterating to this extent the bed of the genital canal, and leaving about eight centimeters of the lower end of the vagina for purposes of copulation. The patient, after a perfectly smooth first week of convalescence, contracted bilateral pneumonia on the eighth day after operation and succumbed to pulmonary œdema two days later. I am thus unable to report the curative and functional result in this, my only attempt at partial carrying out of the operation.

The operation itself may be quite briefly described. The prolapsed uterus and vagina are drawn out between the thighs as far as they will come, and an incision encircling the vagina is made just within the vulva. The vaginal tube is now dissected from its bed in one unbroken piece from the vulva clean up to the uterus, care being exercised to avoid injury of the bladder, ureters, and rectum. Each severed vessel is separately ligated with catgut, mass ligatures tending to interfere with the primary union essential to success. After the vagina has been completely dissected off up to its junction with the cervix, the uterus is cut out in the usual way, catgut ligatures being used to control the bleeding. Uterus and vagina are removed in one piece. I consider it a technical advantage to leave the tubes and ovaries when healthy; if diseased, they should be removed.

We are now ready for obliteration and columnization of the extensive raw surface left in the pelvic cavity as the result of extirpation of the uterus and vagina. The uterine ends of the tubes or, if these have been removed, the infundibulo-pelvic ligaments are brought together and united by a suture of chromicized catgut. A second suture of the same material is passed as a gathering or shirring suture around the entire circumference of the raw surface, about two and a half centimeters below the first. By drawing taut and tying the suture in pursestring fashion the raw tissues from all sides are brought together in the middle line of the pelvic axis, the first suture being pushed upward toward the abdomen just prior to tying the second. A third encircling suture, passed two to two and a half centimeters below and parallel to the second, again gathers the raw surfaces from the periphery of the pelvis to bring them together for union in the center. The second suture is pushed upward, disappears from sight, and is buried as the third is tied beneath it. A fourth, fifth, and as many sutures more as are necessary are passed in a manner exactly alike, two to two and a half centimeters apart, always pushing upward and burying the last tied suture before tying the next, until the vulva is reached. The final suture encircles the bed of the removed vagina just within the vulva. When it is drawn taut and tied the bed of the removed uterus and vagina will have been obliterated. The small remaining slit within the vulva is closed by an ordinary running suture, like all the others of chromicized catgut, and the operation is finished.

I have thus far found it necessary to employ from seven to nine pursing sutures to obliterate the bed of the genital tract. The lengths of the exsected vagina, measured after removal, varied between sixteen and twenty centimeters.

After completion of the operation bimanual examination, made by a finger in the rectum and a hand upon the abdomen, reveals a solid pelvic floor some twelve to thirteen centimeters deep from peritoneum to perineum, the base of the bladder and the anterior surface of the rectum being in intimate apposition to the just mentioned extent.

A piece of bichloride gauze applied over the vulva and retained by a T-bandage constitutes the dressing. The patient is put to bed for a week and then allowed to get up and move about. The catheter is used only when the patient is unable to void urine spontaneously. Immediately after passing urine the external genitals are rinsed with a douche of 1-3,000 sublimate solution.

Simple as the description of the operation reads, I would advise that it be attempted only by one experienced in the plastic surgery of the female genitals. It is decidedly not an operation for the novice. Personally, I have found the safe dissection of the vagina from its bed the most difficult part of the entire procedure.

All the work in my four cases was done from the vaginal side. In my last case a previous high ventral fixation of the uterus came very near compelling me to open the abdomen from above to liberate the uterus from its exceedingly firm attachment to the abdominal wall.

The operation will, of course, have a mortality contingent upon the fact that it will find its chief application in women advanced in life and suffering from the worst forms of prolapsus. What that mortality will be only a larger experience can demonstrate.

I append the histories of the four cases in which I have thus far performed the operation. The first case, in which the operation was performed on the instalment plan, will prove particularly interesting as leading to the fully developed operation practised in the three following patients.

Case I.—M. K., aged twenty-eight, single. First seen May 2, 1892, when the following history was obtained: Well up to five years ago, at which time work involving very heavy lifting was followed by a feeling of uneasiness and weakness in the pelvis. A physician diagnosticated falling of the womb and applied a ring pessary. A year later the cervix appeared at the vulva, and for the past three years the entire uterus and vagina have been continuously outside of the body.

Examination shows complete prolapsus of the vagina and uterus, the prolapsed organs forming a tumor some twelve centimeters in diameter outside the vulva. The uterus is completely outside of the body, the retroverted fundus lying in front of the anus and intestines filling the upper portions of the sac of the vaginal hernia. The position of the uterus made reduction impossible until the retroversion was corrected, and the long axis of the uterus brought into line with the axis of the pelvic outlet. A deep ulceration of the vaginal walls, five centimeters in diameter, was located to the right of and posterior to the cervix. The cervix was greatly thickened and hypertrophied; the uterine canal measured five inches in length. Both uterine adnexa were normal.

First operation, May 6, 1892, consisted of curettage of uterus, amputation of cervix, bilateral colporrhaphy, and ventral fixation of the uterus. It was, if I remember correctly, my first experience with bilateral colporrhaphy. After I had completed the sewing of the lateral vaginal walls, I opened the abdomen to perform ventral fixation, only to find that I could not draw the fundus up to the anterior abdominal wall, the vaginal suturing holding the uterus down in the pelvis. I closed the abdomen temporarily, removed the colporrhaphy sutures, resewed the vaginal wounds, and again opened the abdomen, to find that the fundus could not be brought

up to the anterior abdominal wall. Removing the vaginal sutures a second time, I performed ventral fixation very readily, attaching the fundus firmly and broadly to the anterior wall with three silkworm sutures. The large wounds on either lateral aspect of the vagina were sutured a third time, and the operation was completed.

Second operation, June 17, 1892, consisted of a simple perineorrhaphy to reduce the size of the stretched vaginal outlet, and to form a supporting shelf for the anterior vaginal wall. A vaginal canal two and a half centimeters in diameter was left as the result of these operations.

After convalescence, patient remained in hospital, doing the heavy work of a nurse, until December 2, 1892, without the least return of the prolapse. She married, September 7, 1893, and became pregnant for the first time in February, 1895. On November 24, 1895, after a tedious labor of three days' duration, she was delivered at term of a large, healthy child.

The prolapsus, of which she had remained perfectly cured since May, 1892, began to return in April, 1896, five months after the birth of her child, and was soon as large as before operation.

For more than three years she treated herself, and tried to retain the prolapsed organs by rings and pessaries, until she found, about June 1, 1899, that the tumor outside the vulva was growing in size, and that she could no longer reduce it. She again consulted me, for the first time in years, on July 22, 1899, suffering intensely from local distress, and stating that she had been unable to reduce the prolapse for the past seven weeks, all attempts at reduction being accompanied by unspeakable pains. On examination, I found the entire vagina and the three months' pregnant uterus completely outside the vulva. Reposition of the pregnant uterus into the abdomen was found impossible, even under an anæsthetic; it was too large to pass upward through the pelvic canal.

Third operation, July 25, 1899. Vaginal hysterectomy, for removal of the three months' pregnant uterus. Both tubes, left ovary, and upper third of vagina removed with the pregnant uterus, the healthy right ovary being allowed to remain. Three strong bands or cords, each about two centimeters thick, the result of the ventral fixation performed seven years previously, held the fundus firmly attached to the anterior abdominal wall. A ligature was placed around each, and the cords were severed between the ligature and uterus, freeing the latter. The upper end of the vagina was sewn to the stumps of the ventral fixation bands in the hope that the prolapsed vagina would thus be held in place.

Nine weeks after this operation, the vagina again prolapsed.

Fourth operation, October 24, 1899. Ventral fixation of vagina and inversion of normal vermiform appendix. The abdomen was opened at the site of the former ventral fixation, and the summit of the vagina drawn up into the wound and sewn fast to the muscles and aponeuroses of the anterior abdominal wall.

Two months later the vagina became detached from its fixation to the anterior abdominal wall, and again appeared outside the vulva. For four months the patient endured the distressing condition, when she and her husband begged me to make another attempt at relief. I indicated to them that the only hope of permanent relief lay in total removal of the vagina, and explained to them what that meant as regards their future marital relations. After thinking the matter over for a week, both husband and wife asked that the operation be performed.

Fifth operation, April 27, 1900. Pankolpectomy, after the manner described in the body of the paper. The removed vagina measured fifteen centimeters in length. Eight pursing sutures were required to obliterate and columnize the vaginal bed.

Since this operation, performed just one year ago, the patient has enjoyed perfect health, finally freed from her almost life-long prolapse. Both she and her husband express perfect content with things as they are.

The experience gained piecemeal in this rather unusual case led to the fully developed operation performed upon the next patient.

Case II.—E. R., widow, aged sixty-seven, was kindly referred to me by Dr. W. K. Kubin. She was the mother of four children, since the birth of the last of which, thirty-two years ago, she has suffered from a steadily growing prolapse of the uterus and vagina. The prolapse of both is now complete. For the past five years a prolapse of the lower five centimeters of the rectum has added to her discomfort. An anterior colporrhaphy, performed in November, 1900, had failed to give material relief.

Operation on February 8, 1901, at home of patient. Typical panhysterokolpectomy, as described, was performed. The tubes and ovaries were found healthy and were allowed to remain. The removed vagina measured sixteen centimeters in length. Eight sutures were required to columnize the bed of the removed uterus and vagina. Patient was out of bed on tenth day. Perfectly well, except for prolapsus recti, when last seen, May 22, 1901.

Case III.—S. F., widow, aged fifty-one, had four still-births, the last eight years ago. Soon after this the uterus began to descend. The cervix reached the vulva two years ago. When first seen the cervix protruded five centimeters from the vulva.

Typical panhysterokolpectomy, March 1, 1901. Tubes and ovaries were found adherent, the abdominal ends of the tubes being sealed and club shaped. The adnexa of both sides were removed in one piece with uterus and vagina. The removed vagina measured twenty centimeters in length. Nine sutures were required to obliterate the bed of the removed genital tract. Patient was out of bed on the eighth day. Discharged cured, March 26, 1901, since which time not seen.

Case IV.—For the opportunity to operate upon this case, as well as for the history, I am indebted to the courtesy of Dr. Henry D. Fry of Washington, D. C.

M. F., aged sixty-six, married, mother of six children. The first symptoms succeeded the birth of her first child, thirty-eight years ago, and were followed by the gradual development of complete procidentia uteri. Freund's operation, narrowing of the vaginal canal by submucous buried silver wire ring sutures, was performed in February, 1900. Relief was but temporary, however, the condition returning during an attack of the grippe, accompanied with severe cough. A second operation, ventral fixation of the uterus with added appendicectomy, performed on January 4, 1901, also gave but temporary relief, the cervix soon reappearing outside the vulva.

Operation, May 3, 1901, at the Garfield Hospital, Washington, D. C., with the kind aid of Dr. Fry and the house staff. Typical panhysterokolpectomy was performed, the normal tubes and ovaries being allowed to remain. The fundus uteri was found firmly attached to the anterior abdominal wall. The uterus was stretched to the thinness of a finger and elongated so as to allow the cervix to extend beyond the vulva. The resected vagina measured about fifteen centimeters in length. Eight or nine pursing sutures

were needed to columnize the bed of the removed vagina and uterus.

Dr. Fry writes me under date of May 13, 1901: "Patient did nicely. Temperature reached 100.8°, on afternoon of second day; slightly above 99° for few days. Sat up on seventh day. Will go home in a day or two."

Summary.—The very multiplicity of operations heretofore proposed for the cure of complete prolapsus of the uterus and vagina is proof, if such were needed, that no operator of larger and longer experience is entirely and absolutely satisfied with the results of all his prolapsus operations.

There is room, in the treatment of complete prolapse of the uterus and vagina, for an operation which, properly and successfully performed, will guarantee a certain and permanent cure of the prolapse.

Such an operation is panhysterokolpectomy, the essentials of which consist in complete removal of the uterus and vagina followed by operative obliteration or columnization of the bed of the genital tract.

The tubes and ovaries are not disturbed, if healthy; if diseased, they are removed with the uterus and vagina.

Obliteration and columnization of the bed of the removed uterus and vagina is effected by means of from seven to nine buried pursing sutures of chromicized catgut placed about two to two and a half centimeters apart, and running parallel to each other. Each suture gathers the raw surfaces from the periphery in circular fashion and draws or purses them together in the median line. It is buried by being pushed upward toward the abdomen, while the next suture is being tied beneath it.

The effect of the completed operation is to build a solid pelvic floor ten to fifteen centimeters in depth from peritoneum to perineum, and to establish broad apposition of the base of the bladder and the anterior surface of the rectum, conditions similar to those obtaining in the male pelvis.

The patient is kept in bed for a week after operation. Recurrence of prolapse is impossible after a correctly and successfully performed panhysterokolpectomy.

The operation is indicated in the severest cases of total prolapse, and more especially where other operative procedures have been tried and failed.

The interference with further marital relations must be explained, and accepted by the patient prior to operation. In the case of a married woman the husband must also be consulted.

Four cases have thus far been operated upon by the author of the operation, all with perfectly satisfactory result.

59 WEST FORTY-NINTH STREET

STRANGULATED HERNIA IN INFANTS.*

A STUDY OF SYMPTOMS AND TREATMENT, AND A REPORT OF A THIRD CASE SUCCESSFULLY TREATED BY OPERATION.

BY CHARLES N. DOWD, M.D.,

ATTENDING SURGEON TO THE GENERAL MEMORIAL HOSPITAL, AND TO ST. MARY'S FREE HOSPITAL FOR CHILDREN, NEW YORK.

THE operation for strangulated hernia in infants under one year of age has recently received much attention. A survey of the recent literature[1-15] of the subject shows that at least twenty-five such cases have been reported since May, 1898, and reports of many others could without doubt be found. There was only one death among these twenty-five cases. They, in addition to the one hundred cases previously tabulated[16] by the author, indicate beyond all question that infants endure this operation very well.

Some of these reports indicate remarkable conditions. Guinard and Vernon[3] report the instance of an infant who was prematurely born at eight and one-half months, who was taken from the couveuse two days after birth, successfully operated upon for strangulated umbilical hernia, and then returned to the couveuse. Stoos[14] also operated upon an infant who should have still been "in utero"—he was prematurely born at eight months and relieved of hernia by operation less than a month later. Lilienthal[8] and Erdmann[10] have successfully operated for strangulated hernia on infants respectively eight and thirteen days old. Bainbridge[12] operated successfully for double strangulated hernia in a child four months old. Moschowitz[9] found constrictions in the lower part of the sac in two cases, which suggest an explanation for the strangulation in certain instances.

Fraenkel[11] operated upon four nursing children—two of them in out-patient practice—and the results were so satisfactory that he advocates operations even for reducible hernia in nurslings, and records twelve such cases among sixty-eight hernia operations in children. Hirschkopf,[13] in reporting the hernia operations from Kocher's clinic, also advocates operating on nursing children for reducible hernia, and quotes Kocher, Broca, and Tillmans to support his view. These references are given, not to advocate such a procedure, but to show the trend of surgical opinion as to the ability of infants to endure operation. Karewski[14] probably voices the sentiment of the majority of surgeons when he states that, although infants bear operation well, they also do well under truss treatment, and this should be tried as a routine practice when they have reducible hernia.

An additional case which has come under the writer's care presented peculiarities that are worthy of note—the intestine had almost slipped back into the peritoneal cavity, leaving no palpable tumor, although the strangulation persisted. The operation was done on account of the symptoms and history. The child was a strong boy, three months and ten days old, who was brought to St. Mary's Free Hospital for Children April 4, 1900. Two weeks previously the mother had, for the first time, noticed a right inguinal scrotal hernia, which remained down for two days and was then reduced by taxis. On April 2 the scrotal swelling reappeared and the child became cross and peevish, and began to vomit. On April 3 there was stercoraceous vomiting, and there was no movement from the bowels after repeated enemata. On the morning of April 4 the tumor had disappeared, but the child seemed sick and was brought to the hospital.

On examination no hernia could be found; the tip of the finger was pushed into the external abdominal ring; a finger was also introduced into the rectum and careful bimanual examination of the inguinal region made, but no hernial protrusion could be distinguished, although thickened tissue could be felt extending from the external ring toward the scrotum. Since the child had not vomited for several hours and had nursed twice during that time, it was hoped that the hernia had really been reduced. The general condition was not bad, temperature 100°, pulse 120, abdomen slightly distended. A high enema of water was given, but brought away no fecal matter.

Two hours later he began to vomit light-yellow semifluid material with a fecal odor, and operation was done with the least possible delay. The ordinary Bassini incision was made; the sac was found

*Read in part before the West End Medical Society, February, 1901.

to be dark colored, almost gangrenous, and was firmly adherent to the surrounding tissues. The aponeurosis of the external oblique muscle was cut through from above and the constriction thus relieved. The sac was then opened, and a very small knuckle of intestine was found to have been obstructed at the external ring. The constriction just included the lumen of the intestine, but no more. This occluded portion of the intestine was dark colored, and there was a flake of fibrin on it about half an inch in diameter. The circulation was quickly restored and the intestine returned to the abdomen. The sac was inflamed and matted to the cord, so that it could not be separated; at this time stercoraceous vomiting came on again; hence the routine steps of the Bassini operation were impracticable. The sac was closed by a ligature of chromicized gut and the split in the external oblique aponeurosis was sutured with the same material. The skin and superficial fascia were brought together above and left to drain below, provisional sutures being placed so that the tissue could be brought together at a later time. The child had copious movements from the bowels within six hours, and recovered without incident. The packing from the wound was loosened, and the provisional sutures were fastened on the second day. The child left the hospital on the eighth day, and healing by granulation took place promptly.

This case calls our attention particularly to certain points in diagnosis—operation was done because the history indicated that there had been a strangulated hernia and because the child continued to vomit stercoraceous material even when the hernia had apparently been reduced—the records indicate that in many instances operation has been delayed because of difficulties in diagnosis; a baby who cannot talk, who cries for various discomforts, and who has a thick pad of pubic fat, which may easily obscure a small hernia, presents many difficulties in diagnosis. In order to study the symptoms in the infants who have been operated upon for strangulated hernia, I have, with the help of Dr. A. G. Hilke, had the symptoms of these one hundred and twenty-five cases tabulated, so far as they are accessible, in the library of The New York Academy of Medicine. The records as to symptoms are very incomplete, but in forty-seven cases they are sufficiently explicit to be available for the purposes of this tabulation. It is to be remembered, however, that the failure to record a given symptom does not always indicate that this symptom was not present. The tabulation probably indicates approximately the relative frequency of the symptoms. The presence of a swelling or tumor was mentioned in forty-four instances. Vomiting occurred in thirty-eight cases; in one instance it continued during four days; in seven instances it continued during three days; in four more instances during two days; it was described as stercoraceous in ten instances.

Constipation is mentioned in thirty-two instances; in one case it existed seven days; in ten instances it existed three days or more.

Inability to urinate, of greater or less duration, is mentioned in nine instances; Tietze[17] has attached much importance to this symptom, and it has probably existed for a certain time in many instances in which it has not been recorded.

Pain is a symptom which cannot be accurately determined in infants, but the crying and fretting is spoken of in twenty of the cases. Of course, it probably existed in all of them. Constitutional depression was severe enough to excite comment in eighteen of the cases.

The relative importance of the symptoms is apparently in the order which might have been expected: (1) Tumor; (2) vomiting; (3) constipation; (4) difficulty in urination; (5) restlessness and apparent pain; (6) constitutional depression. The occurrence of symptoms which might be considered out of the ordinary course was very unusual.

The records indicate that delay in the effort to interpret symptoms or reduce the hernia by taxis has been the greatest danger, while early operation has been the greatest safeguard.

On seeing the case here recorded, at the termination of a year, a recurrence of the hernia is found to be present, which is easily controlled by a truss, and which, without doubt, can be cured by the truss or by another operation. This does not indicate that the method used was not the proper one for this especial case—an infant who is vomiting fecal matter is not a suitable subject for a prolonged operation, even if the isolation of the sac were possible. It does, however, indicate that infants should have as thorough an operation as is practical in the effort to secure a radical cure.

Karewski and Eccles advocate the ligation of the sac rather than the performance of the routine Bassini operation in infants. Since this hernia recurred after the neck of the sac was securely included in a chromicized gut ligature, and the split in the external oblique aponeurosis was united by similar sutures, it seems to the writer best always to do the routine operation for the radical cure of the hernia unless an inflamed condition of the tissues or extreme prostration or fecal vomiting render further procedure unwarranted.

115 WEST SEVENTY-THIRD STREET

A STUDY IN HEREDITY: IN ITS RELATION TO IMMUNITY AND SELECTIVE ACTIVITY IN TUBERCULOSIS.*

BY HERBERT MAXON KING, M.D.,
GRAND RAPIDS, MICH.
DELEGATE FOR THE MICHIGAN STATE BOARD OF HEALTH TO THE BRITISH CONGRESS ON TUBERCULOSIS, 1901

THE material for this study was taken chiefly from private practice, with the addition of a few cases occurring in the author's hospital service, in which opportunities for close observation at the time and personal knowledge of the subsequent histories of the several cases after leaving the wards were sufficient for the purposes desired. Some apology it would seem necessary to offer for presenting before such a body as this honorable congress deductions and conclusions based upon researches in so limited a number of cases as this present study includes, more especially since certain of the conclusions are

*A paper read before the British Congress on Tuberculosis, held in London, July 22–26, 1901.

at variance with traditional axioms in phthisiology. However, in the present inquiry all facts were collected and recorded personally and without prejudice, so that, however unique may be the conclusions to which a study of my cases has led, they are warrantable at least so far as the limit in number of observations will permit. The material at my disposal consists of carefully recorded histories of two hundred and forty-two cases of pulmonary tuberculosis. In every instance I have endeavored, besides studying the influence of heredity and environment, to ascribe, whenever possible, a cause for such peculiar manifestations of the disease as became apparent, and also to establish the relation which certainly exists between the selective activity of the disease and hereditary influence.

The theory that a phthisical parentage predisposes the offspring to the disease by virtue of heredity, while very firmly grounded in the medical mind, and still more so, of course, in that of the laity, has nevertheless, I believe, always been a subject of more or less controversy, and especially since the isolation of the specific microorganism. Without, however, entering upon a *resumé* of this controversy, which the limits of the present occasion and inclination alike proscribe, I have, like most phthisiotherapeutists, always been disposed to discredit the theory and, until within the last four or five years, to place a negative value upon "family history" except in so far as a tuberculous parentage subjected an individual to additional risks of infection. The following instance, which came to my notice several years ago, first suggested to me that there might be a certain degree of *immunity* conferred to the offspring of phthisical parents. I published this instance as an illustration in 1898, in a paper in which I first ventured the opinion that "phthisical parents might impart to their progeny a certain immunity to the disease."[1] As it is brief and to the point I quote it: "A clergyman and his wife, the latter having borne two children after developing pulmonary tuberculosis, took into their household by adoption the orphan child of a non-tuberculous family. After surviving the birth of her last child six years the wife died. Both of her children are living and in excellent health to-day, the younger having passed her twentieth year. The adopted child came under my observation at the age of seventeen years, having developed acute pulmonary tuberculosis, from which she died."

To adopt as a working theory this idea of conferred immunity in tuberculosis against all traditions requires, I admit, considerable temerity. One is constantly confronted with the question of inherited predisposition and cannot fail to be influenced by the demonstrable fact of "percentage heredity," a term employed by Dr. J. Edward Squire to express in percentage the difference between the number of the offspring of consumptive parents subsequently developing tuberculosis and that of the offspring of non-consumptive parents subsequently developing the disease. Dr. Squire's paper was published in November, 1897,[2] and was a most valuable contribution to the subject of hereditary influence in phthisis. In it he refers to a former paper, by himself, read before the Royal Medical and Chirurgical Society of London in December, 1894, on "The Influence of Heredity in Phthisis." Both papers were based upon results of thorough investigations in sufficient numbers of instances to warrant the adoption of his conclusions as *standards* in future inquiry along this line. I have no hesitation in accepting them as final so far as they are carried.

This "percentage heredity" Dr. Squire found to be only 0.51, and he points out that it is easy to explain this small percentage of influence due to parents by the additional risks of infection to which the children of phthisical parents are exposed. Now it has seemed to me almost certain, that if these children of consumptive parents, especially that usually weak and under-nourished class from which Dr. Squire made his observations, were not in some manner protected, this percentage would be much larger, since in such cases we may take it for granted that all of them fulfil every required condition for the development of the disease. Therefore, while admitting the fact of a "percentage heredity," the very figures which express it are such as to support the theory of an hereditarily conferred immunity.

It is, I think, the rule to find among the children of consumptive parents poor nutrition, imperfect digestion, and other functional derangements, together with certain almost characteristic marks of degeneracy in the bony skeleton, the long, shallow and comparatively immobile chest, prominent scapulæ, and sunken sternum. Yet with such features, more or less marked in a family of several children of consumptive parentage, it is a matter of common experience to see them all reach maturity without succumbing to an infection which, from the very nature of things, it would seem inevitable that they could not escape; while, on the other hand, the more acute, unresisting, and progressively fatal cases, I think, it is the common experience to find among those of a much more normal physical habit and where the source of infection is frequently most difficult to locate. Observations of this character, however, prove nothing, of course. It is from the analysis of a given number of cases occurring under somewhat similar conditions, and among individuals of like hygienic and social relations, that statistics, to be of any value, must be drawn. Even so obtained, statistical figures are very apt to be misleading and are no doubt open to much just criticism on that score. I would not attempt to prove a theory by conclusions based upon an experience in two hundred and forty-two cases unless the results were very positive, but I would very much like to provoke discussion of a subject which cannot be devoid of interest in such a society as this Congress represents and to stimulate further inquiry into a matter of such far-reaching importance. If I shall have accomplished this object I shall rest content with the assurance that the theory will take care of itself.

To proceed, then: the cases which I have utilized in this series have occurred in a community for the most part moderately well-to-do—small tradesmen, mechanics, artisans, operatives in wholesome, well-lighted, clean, and well-ventilated furniture factories, and small farmers. Nationality has been various. Next to American born, Dutch, German, Scandinavian, and Irish predominated. Because of the comparatively recent development of the section of the country in which my observations have been made, and the more or less migratory habits of the first generation or so of foreigners in America, it has been the exception rather than the rule to be able to secure accurate data beyond the immediate parentage; but while it would be desirable to secure such data for purposes of demonstrating the transitory character of inherited immunity in tuberculosis, if such exists, for present requirements it is, I think, needless to do so.

The individuals comprising my series, by reason

1. *Medical News*, December 3, 1898.

2. "Heredity in Phthisis," *American Journal of the Medical Sciences*, November, 1897.

of their comparatively well-to-do condition and the customs prevailing in the locality, have none of them experienced the vicissitudes incident to life in the cheap tenement-house districts of larger cities. As a rule this class lives in small, compact but well-lighted and comparatively new frame houses, separated from each other by lawn spaces, and heated by stoves, or occasionally by hot-air furnaces. In the course of inquiry, when phthisis was found in either or both parents, it was the rule, with very few exceptions, to find it to have been present during the early life of the case under observation and to have been the cause of death. Frequently it could be traced back prior to the birth of my patient and to have persisted with remissions in activity for a considerable time afterward; more particularly was this the case among women, where in several instances I have satisfied myself of its presence during most of the child-bearing period. Without exception, these instances occurred among women of consumptive parentage. Of course, positive demonstration of the long existence of the disease in these cases was obviously impossible beyond the time of my own acquaintance with the case, and as scientific evidence, therefore, such citations are valueless.

Of my two hundred and forty-two cases, the parents, one or both, had phthisis in sixty instances, or 24.8 per cent., while the parents were non-phthisical in one hundred and eighty-two instances, or 75.2 per cent. Of the sixty who had phthisical parents, the father was found to have been affected in thirty-one cases, or 12.8 per cent.; the mother in twenty-nine cases, or 12 per cent., and both parents to have been phthisical in four instances, or 1.6 per cent.

It was more common in my experience to find a previous tuberculosis in a brother or sister or both than in the parents, and in such cases an almost perfect history of infection could be traced. It was often possible to designate the date of infection to within a few weeks, and in some instances to within even narrower limits, a point of some value in estimating the period of incubation, or studying that questionable quantity, the "period of latency."

Seventy-four of my cases, or 30.6 per cent., gave a history of previous tuberculosis in a brother, sister, or both, and it is a point of some interest that of these seventy-four only twenty-two were of phthisical parentage; furthermore, as will be recalled there were sixty cases in which one or both parents were phthisical, and of these twenty-eight had brothers or sisters who were non-phthisical; or, to put it a little differently, out of sixty families with phthisis in one or both parents, there were twenty-eight instances of the disease affecting only one of several children. This does not, of course, imply that in the remaining thirty-two there was necessarily more than one child affected, for in many instances the patient was an only child. It will further be seen that while twenty-two individuals having a phthisical parentage gave a history of previous tuberculosis in one or more brothers or sisters, there were fifty-two cases of non-phthisical parentage giving such a history.

These figures would certainly fail to show an hereditarily conferred predisposition to the disease, and if they have any value at all, it is on the side of a conferred *immunity* instead. Of the whole number—two hundred and forty-two cases—I can, at present, account for two hundred and thirty-five; of these one hundred and thirty-two are living, and one hundred and three have terminated fatally. Although it has a negative bearing upon the present inquiry, it may be of interest to note that in each group the percentage of phthisical parentage is the same; that is, of the one hundred and thirty-two living, 26 per cent. had phthisical parents; and of the one hundred and three dead, there was also 26 per cent. whose parents, one or both, had died of the disease.

The most interesting development in the course of this investigation has resulted from a study of the one hundred and three fatal cases. As above suggested, 26 per cent., or twenty-seven cases, were found to be of phthisical parentage, while seventy-six had non-phthisical parents. My histories show that the *average* duration of the disease from its apparent incipiency to the fatal termination was, in the incidence of the twenty-seven cases of tuberculous parentage, 4.01 years, while in that of the seventy-six cases of non-tuberculous parentage it was 2.03 years, a difference of more than a year in favor of those having a phthisical parentage.

Now, it has been my experience that the development of phthisis in individuals living or having lived for any length of time with consumptive parents is more subtle and indeterminate as to commencement than is the case in the more robust offspring of non-consumptive families, where the onset of the disease is far more apt to be comparatively sudden, and consequently more easily determinable as to date of commencement. In this latter class the so-called "pre-tuberculous stage" has no existence as a rule, and the measurement of the duration of the disease is accordingly much simplified. This "pre-tuberculous stage" is, in reality, I am sure all will admit, a part of the life history of the disease and *should* be included with all subsequent stages of phthisis when estimating duration of the disease in a given case; but because I desired to free my inquiry as far as possible from misleading results or error in judgment as to what was and what was not the early stage of tuberculosis, I have, in this series of observations, limited the definition of phthisis to a stage of the disease where it has been clearly demonstrable. I have, therefore, a considerable leeway over and above the one year in favor of my cases with consumptive heredity, and had I included the "pre-tuberculous" stage in my estimates I am very certain that the difference in duration of the disease between the two classes would have been more marked than it is. I have, like many other observers, frequently demonstrated the presence of tubercle bacilli in the secretions of the air passages of healthy children and adults occupying apartments with consumptives, particularly consumptive parents, when subsequent events failed to show a development of tuberculosis from their presence. As an illustration: In a family consisting of a widow and four adult children, one of whom, a daughter, has been a consumptive for seven years (easily demonstrable during the whole of that time), the father had died after having had phthisis for upward of twenty years. The consumptive daughter above referred to continued the local focus of infection after the death of the father, although to a less dangerous degree because of sanitary education. A few years ago one of the sons contracted typhoid fever, during the course of which the usual bronchitis developed. In the expectorated matter many tubercle bacilli were found during the course of the complication. Doubting the diagnosis of typhoid, I verified it by a positive Widal test and the diazo-reaction in the urine. There was no pulmonary consolidation and the case ran a typical course with good recovery and, to my surprise, the patient has never shown the least evidence of tuberculosis since, although during several subsequent winter attacks of bronchial catarrh a search has been made for bacilli. I might add

that in this family every one of the four children is apparently a classical subject for phthisis, with the long, shallow, and immobile chest, and the imperfect nutrition above remarked; yet, though having lived almost their entire lives in the house with a consumptive, only one has developed the disease, and that one presenting every evidence of being able to resist a fatal termination successfully for many years to come.

Vital statistics show a gradual declining death rate from phthisis. This is, doubtless, in part the result of improved methods in restricting the spread of the disease, but, in view of many facts, is no doubt also due in part to one or both of two not unimportant factors, *i. e.* natural selection and inherited immunity. If the conclusions reached by Otto Naegeli, based upon five hundred autopsies made in the Pathological Institute of Zurich, on bodies of individuals dying of various diseases, shall be verified in other parts of the world, the question of inherited immunity must be acknowledged to play a very essential part in the decline in frequency and severity of phthisis. Naegeli found indubitable evidence of active or latent tuberculous lesions in 0.7 per cent. of all sections in individuals between eighteen and thirty years of age, and in 99 per cent. of those over thirty years of age.[3]

If it is true that nearly all individuals reaching thirty years of age develop tuberculous lesions which are demonstrable *post mortem*, the only explanation for the comparatively small percentage who die from phthisis lies in that of an inherited or acquired immunity.

Within the memory of men still living there was no phthisis among the Indian tribes roaming the high plateaux of Colorado, Arizona, and New Mexico. But a very few years after it became popular to send white consumptives to those regions as a therapeutic measure, the infection thus spread among the Indians gave rise to an almost epidemic form of phthisis of an unusually acute and fatal type. The same is true of the negroes of certain sections of the Southern States, whose heredity was entirely clean so far as tuberculosis is concerned, yet who succumbed in prodigious numbers as soon as the infection was brought them by the consumptive whites from the North, who, by reason of their greater immunity, often recovered by virtue of a climatic influence which, like that of Mentone, was insufficient to protect the non-immune native.

The older writers, in speaking of the influence of family history in phthisis, often remarked upon the frequency with which the disease affecting the grandparents would skip one generation to reappear in the grandchildren. If there is truth in such a statement, it would seem plausible to attribute the phenomenon to an inherited immunity sufficient to protect the children, but not sufficiently permanent to protect the second generation. In my own experience I have not attempted records with this idea in view, and therefore have no facts to bear it out.

I must acknowledge one rather serious omission in the course of my investigations in the present series of cases. It was, to a certain extent, unavoidable, but in future inquiry along this line it seems to me most important that it be not again omitted if we are to arrive at any positive conclusions by such methods as I have employed. It lies in my failure to determine whether or not, when there was a consumptive parentage, the parent affected was tuberculous prior to the birth of the patient under consideration; for if such were not the case, and the parent became tuberculous only after the child was born, obviously any immunity to the disease which the child afterward developed would be simply an acquired one; and if the child afterward became phthisical, the disease in the parent would have no more bearing upon the case than had it occurred in a brother or sister. In such a case it would be quite proper to include it in the class of non-phthisical parentage, for the purposes of present study.

Briefly then, to summarize the results of observations in my series of cases, it will be remarked that: (*a*) Of two hundred and forty-two consecutive cases of phthisis, approximately one in every four gave a history of phthisis in the parents. (*b*) Nearly one in three gave a history of previous phthisis in a brother, sister, or both. (*c*) More than two-thirds of those giving a history of previous phthisis in brother, sister, or both had non-phthisical parents. (*d*) As a rule, in the incidence of individuals of phthisical parentage afterward developing phthisis, a much longer period was found to exist between the supposed exposure to infection and the subsequent appearance of the disease than was the case in the incidence of those giving a non-phthisical heredity. (*e*) Of one hundred and three fatal cases of phthisis, the average length of life after development of the disease of those giving a history of phthisis in the parents was to that of individuals of non-phthisical parentage approximately as four to three.

So that, from a study of the foregoing series of cases, the following conclusions naturally follow: 1. The percentage of consumptives having a tuberculous parentage is actually smaller than that having a non-tuberculous parentage, and much smaller than would be more than accounted for by the additional risk of infection to which the former class is subjected. 2. Tuberculosis in the parents renders to no inconsiderable extent an immunity to the disease in the offspring, an immunity which of course is but relative, and not sufficiently protective, but still demonstrable, as is shown by increased resistance to the progress of the disease and increased tendency to recover among this class.

EPILEPSY: ITS ETIOLOGY AND TREATMENT.*

By J. L. BOWMAN, M.D.,
UNION SPRINGS, ALA.

Of the many diseases whose etiology is obscure and whose treatment leads us into the realms of empiricism, there are few upon which more theories have been advanced and more therapeutic agents recommended, according to the experience of different observers, than epilepsy, yet there is scarcely any more common disease in general practice.

Perhaps no little of this indifference is due to the utter failure, in many cases, to secure any relief for our patient by the *vis medicatrix* at our command, and the further knowledge that authorities differ so widely, a fact that may be explained by considering the point of view which each writer takes of the subject.

The neurologist terms it a functional disease of the gray cells of the cortex, the surgeon, a disease demanding surgical interference to suit some favorite operation, while authorities on general medicine find many causes for the discharges of nervous energy known as epilepsy, unquestionably justify-

*Read before the Bullock County Medical Society, July 3, 1901.

ing the statement that the disorder is as complex as hysteria (Spiller).

Etiology.—We find that three-fourths of the epileptics are affected before the age of twenty; 12 per cent. before the third year, while in nearly half of the cases the disease manifests itself between the ages of ten and twenty. The greater number of these appear during the fourteenth, fifteenth, and sixteenth years (Gowers). The changes of puberty, therefore, appear to influence at least the manifestation of this disease, and this is to be expected, since at this time the growth of the brain is at its maximum and the associative centers are attaining their full development (Berkley), hence are more responsive to any excitant.

A more sensitive nervous system in females during and after puberty renders them more liable to the affection than males, and there is a ratio of females to males about six to five, though males predominate before puberty. Heredity is, however, the most important factor in the etiology of this disease, for as the poison of the syphilitic, the nervous debility of the alcoholic, the susceptibility of the tuberculous parent is transmitted to its progeny, so does the epileptic inherit a tendency—an irritability of the central nervous system which many causes may excite, and which, once excited, responds to the least stimulation in the crises of epilepsy. Two-thirds inherit (Gowers) this tendency from parents manifesting nervous instability by suicide, hysteria, chorea, neurasthenia, insanity, general paralysis, or epilepsy, dissimilar heredity being more frequent than similar (Féré). Epilepsy due to traumatism in parents may be followed by epilepsy in children (Féré). Perhaps the number who inherit the tendency to the convulsions would be greatly increased were we to consider infantile eclampsia or other acute eclampsias in the parents, or could we know their constitutional weakness, which on account of early death from acute disease may not be revealed. For instance, in a family in which six children were epileptics no nervous precedents could be found until at the age of eighty the father died with acute melancholia. The children of alcoholics and syphilitics are specially liable, while drunkenness, poisoning by lead or mercury, morphinomania, infectious diseases, sexual excesses, and like debilitating causes in one or both of the parents at the time of conception (Féré), and in the mother during pregnancy, are important factors in the production of epilepsy in the offspring.

Some authorities class all convulsions in which the exciting cause is known according to that cause, reserving the name epilepsy for the idiopathic form only, while, on the other hand, some are inclined to consider as epilepsy all convulsions which give us the same symptomatic picture, acute or chronic, believing that epilepsy is but a symptom complex produced by the most varied causes.

We shall assume, however, that we have one factor given, viz., *an inherent tendency to convulsive discharges*, and seek to discover the exciting cause.

The apparent cause of the first attack is usually given as the exciting cause, though in many cases this is doubtful or incorrect. It is said that only 40 per cent. of the cases have even an apparent cause. We know, however, that injury to any part of the cerebral cortex may excite the recurrent spasms and that they more frequently follow light blows or falls on the head than severe traumatism. Kocher, who believes that the crises are due to increased intracranial pressure, explains this fact by the formation, by a fracture, of a safety valve, as it were, and bases his statements on experiments upon guinea pigs, in which he found that light blows upon the head would produce convulsions unless the skull had been opened.

Meningeal hemorrhage is likewise a cause, but if Kocher's theory be true it will be clinically impossible to say whether the hemorrhage was the cause or the result of increased blood pressure. The latter would seem the more probable. Other organic lesions (thrombi, emboli, and tumors) cause recurrent spasms.

Microcephalia and hydrocephalus are given as frequently causing this disorder, but after all we may have the identical pathological condition in two persons and the one have epilepsy while the other escapes. Even in microcephalia only one-third of the cases have convulsions (Berkley). Does this not emphatically suggest, if not prove conclusively, that the convulsive tendency must be present or other pathological conditions will not produce the eclampsia?

Disorders of nutrition are to be considered, and the statement has been made that light blows on the head, fright, acute infectious diseases, syphilis, and rickets cause this disease by affecting the nutrition of the brain cells.

Rachitis is the most important predisposing cause of infantile convulsions (Holt), and three-fourths of the epilepsy beginning in infancy shows itself first in infantile convulsions (Gowers). We have no record of how many there are in whom the disorder manifests itself after a history of infantile eclampsia. In fact, the similarity of symptomatic pictures, the hereditary influence in each, and the frequency of eclampsia in infancy in the history of confirmed epileptics give the diseases a very close relationship, if they are not identical. Baumes says that the only difference in the two is the difference in the course, which only time can establish. Why then should we distinguish between the two more than any other acute and chronic forms of a disease? We have, however, these two diseases very closely allied, one, to say the least, an etiological factor of the other and rickets a basis for each. Along with rickets or apart from this disease, anæmia and inherited syphilis prepare the nervous system for the recurrent discharges, primary syphilis never causing epilepsy except by central lesions. The acute infectious diseases frequently mark the onset of epilepsy, notably scarlet fever, measles, and typhoid fever, in the order of frequency. I have seen a case of petit mal follow an attack of typhoid fever. It is to be noted, also, that the convulsions of these diseases are pictures of epilepsy and of the same order, and certainly seem to depend on an inherent tendency, since, other conditions being the same, one patient will have convulsions and another will not.

Renal diseases, apart from uræmia, and in rare instances diabetes mellitus, are probable causes of epilepsy. The uræmic convulsion is attributed to the action of a poison in the blood on the central nervous system giving typical crises of epilepsy, though we do not term it epilepsy, since we think we know the true exciting cause. Further investigations tend to show that there are other poisons, the result of defective metabolism or other morbid process whose accumulation in the blood causes, in many cases, the so-called idiopathic epilepsy. Herter and Smith found in two hundred and thirty eight specimens of urine from thirty-one epileptics, at the time of convulsions, large amounts of the ethereal sulphates, indicating intestinal putrefaction, in 72 per cent. of the cases. We may, therefore, conclude that autointoxication, usually associated with chronic constipation, plays at least a part in the production of the paroxysm (Holt). Of the

limited number of patients coming under my observation, nearly all have required treatment for constipation and were of the lymphatic temperament. This latter condition Olmacher believes to be a basis for this disorder. In this type of persons we usually have indigestion and constipation, hence autointoxication, anæmia, and deficient oxidation.

Indigestion, gastric and intestinal, *per se*, in some cases causes the paroxysms (Delasuave). A case under my care some time since will illustrate this: A girl of six years, with a history of insanity and neurasthenia in the family, had recurrent convulsions. These were preceded by an aura of three or four hours' duration characterized by drowsiness and interrupted by apparent fright. An emetic during the aura prevented the paroxysm, as did vomiting, which supervened at times without the aid of an emetic. A sound sleep of several hours followed—all these being symptoms typical of epilepsy. In this case there was certainly the innate tendency manifested and the indigestion or the improper food furnished the excitant. With this cause removed, some other may in the future bring about a return of the paroxysms.

Haig believes uric acid to be the cause of epilepsy, and Krainsky was able to show in his experiments a ratio between the subnormal amount of uric acid excreted and the number and intensity of the convulsions, but since the convulsion could not be produced by the introduction of this substance into the system another cause must be found. This observer was then able by further research to demonstrate carbonate of ammonia in the blood of epileptics, and in comparatively large quantities in the status epilepticus. This substance injected into the blood will cause the paroxysm. It is formed at the expense of uric acid, and during the attack is broken up into urea and water, giving us the chemical equation:

$$H_2NCO,ONH_4 = H_2O + CON_2H_4.$$

We might further conclude that the convulsion is necessary to produce this change, since in those patients who sometimes suffer from psychic seizures (dumb fits) the mental disturbance following is much greater than after the ordinary convulsion, suggesting that the cause of the disturbance is not entirely removed. We can very readily conceive this to be a product of defective metabolism due to (1) fermentative disturbances in the alimentary tract and imperfect digestion, (2) imperfect oxidation, or (3) trophic disturbances over which the central nervous system has control. Among the causes in the first class, we would have teething, improper food, and indigestion, intestinal parasites, constipation, rickets, etc.; in the second, anæmia, with resulting affections, dysmenorrhœa and amenorrhœa, the puerperium, lymphatism, injuries, and obstructions affecting the respiratory apparatus, etc.; in the third, blows and falls upon the head, organic lesions, sunstroke, fright, mental stress, peripheral irritation, such as phimosis, irritation of the large nerve trunks, etc. Chronic poisoning by lead, opium, alcohol, or cocaine, and syphilitic and other toxins act in a measure in all three classes, yet each one in itself is a sufficient irritant to cause the convulsions.

Defibrinated blood taken from a patient during an epileptic attack and injected into a guinea pig causes convulsions and later death if a sufficient quantity is used (Kramsky). This result is not secured in all cases, from which we may conclude that, in some instances, there is either no toxin present or one which, affecting man, has no effect on the animal, or that the particular animal may have less tendency to convulsions and therefore withstands the irritant, as there are no doubt many individuals who, having all other conditions, but lacking the irritability, have no paroxysm.

The sight of a corpse, of blood, or the realization of immediate danger is not infrequently the cause of a seizure, and in certain cases the only cause, the stimulus in these cases being external. Whether or not circulatory disturbances in the cortex are produced by this is yet to be ascertained.

Diseases of the eyes and ears may produce epilepsy, and even a lump of hardened cerumen or other foreign body in the external auditory canal has caused this disorder (Randolph).

Nothing has been said of idiopathic epilepsy because the object of this paper is to suggest lines of investigation by which we may hope to remove this class from consideration. I offer, then, this definition, which seems to me to define the disease according to our present knowledge:

Definition.—Epilepsy is an affection of the nervous system, characterized by convulsions with or without the loss of consciousness. The reverse may be true, and there may be a simple giddiness or sensation. It is due to an irritability of the gray cells of the cerebral cortex, innate and probably hereditary, these cells being acted upon by some irritant, external or internal, physical or psychical.

Treatment.—Considering the basis of this disorder, inborn if not hereditary, we cannot hope to remove the tendency of the paroxysm to recur, other conditions favoring, any more than we can hope to render one inheriting a tuberculous diathesis immune to pulmonary disease. Since one attack renders an individual more liable to another, we must turn our attention to the prevention of the first paroxysm.

A considerable number of cases due to rickets, teething, and malnutrition beginning in infancy might be prevented by proper feeding (Gowers). Care during the acute infectious diseases, as well as proper diet at all times, will prevent the onset of infantile convulsions, and regular habits may prevent the onset of epilepsy through life.

When the disease has once begun, we have some irritant to deal with, physical or psychical, and to remove if possible. Peterson's advice is to find the cause and remove it. This is the very thing to do when practicable. In any case it is best to begin by treating the mind of the patient; make a profound impression. Perform some minor surgical operation where indicated, which will thus serve a twofold purpose. Make the patient hopeful; remove from him the occasions of anxiety; study the mind and meet the indications as far as possible.

General hygiene is of special importance. The necessity of regular habits cannot be too strongly emphasized—regular hours for eating, sleeping, physical and mental exercise, bathing, etc. Indeed, I believe there is no other disease in which the treatment will be aided so much by the patient living, as it were, by the clock. I had under my care a patient in whom the paroxysms were always brought on by the loss of several hours' sleep; these paroxysms, by the way, usually causing the dislocation of one or both shoulders, at first by violence later by muscular contractions.

The great majority of epileptics have enormous appetites and many are excessive meat eaters. From my observation, I think the larger number of these sufferers should abstain from meat, if for no other reason than that meats are so difficult to prepare, at least are so rarely prepared properly. The proteid food should be supplied by eggs, milk, and the vegetable proteids. Certainly the diet

should be readily digestible, unstimulating, nutritious, and in quantity fully up to the needs of the body, but not excessive, and the food should be, I repeat, taken at regular hours. Not only is a stimulating diet to be forbidden, but also stimulating drinks, and especially alcohol in all forms, however light. Instances are recorded in which the paroxysms returned, after an absence of months, when a glass of wine had been taken.

Light exercise is to be recommended. The occupation of the epileptic should be one in which there is no danger in event of sudden onset of the spasm (among machinery, etc.); at the same time there should be employment both of mind and body sufficient to keep him in a healthy condition.

The bath, indispensable as it is both in health and disease, is of a special value in both the hygienic and therapeutic management of this malady. The cold bath, given morning or evening, or both, followed by friction to secure reaction, should be inseparably connected with the treatment of epilepsy and later with the life of the epileptic. It acts as a nerve and vascular sedative, keeps the skin active, thereby relieving the other excretory organs, and has a tonic influence on the whole system.

On entering upon any special treatment we must carefully examine the patient for any source of irritation and remove it. Eyes, ears, nose, and throat are to be given attention lest asthenopia, Ménière's disease, foreign bodies, or adenoid vegetations cause the convulsions and go unobserved. The history and habits are to be noted as well as the general condition of the patient, and whatever of surgical treatment is indicated should be given as early as possible.

Operations on the cortex are to be considered in certain cases of partial and traumatic epilepsy, but these are to be carefully selected. McCosh has formulated the following rules defining such cases, which are certainly safe to follow:

"1. Focal lesions or partial epilepsy, where convulsions are limited to a particular group of muscles.

"2. In epilepsy, general or partial, when the condition has followed or was apparently caused by traumatic depression.

"3. In many cases where partial epilepsy has followed head injury, even though there are no external indications, but in which signal symptoms indicate the brain area affected."

The epilepsy should not have existed more than two years (Sachs and Gerster) and even then statistics do not show the results of operations to be as favorable as one might expect. Removal of a portion of the cortex is justifiable when a certain group of muscles is involved, provided the center can be accurately located. Paralysis is the inevitable result, but is preferable to the spasm which is likely to become general. It must be noted, however, that the removal of a portion of the cortex, *e. g.* the hand center, in a case of partial epilepsy affecting the hand, and a resulting cure, does not prove that the excised cells were the sole cause of the convulsions, since hypersensitive cells in this center may have responded to irritation and stimulation from other sources.

Of the many operations not directed to the immediate or local cause is to be mentioned Kocher's operation, viz. trephining and removal of bone and dura, so that the bone will not reform, but the space fill with a soft yielding mass, furnishing, as it were, a safety valve for intracranial pressure. Jonesco, Chipault, and others resect the cervical sympathetic ganglia on the theory that the convulsion is due to cerebral anæmia, and Jaboulay stretches the pneumogastric nerve; both of which operations DaCosta pronounces "too profoundly scientific to be safe or successful." After all, it is to be remembered that any major or minor operation may interrupt the recurrent paroxysms for months and even years, when to our dismay they return. I think, in such cases, the operation has had some direct effect on the cause, but the tendency remains and the same or other conditions in the future give rise to the relapse.

Of all internal remedies for epilepsy the bromides are the most popular, probably because of their apparent and immediate benefits. The physiological action of the bromides in this disorder, I think we may conclude from the experiments of Kohrman, consists in a lowering of the activity of the motor cells, then, after large doses long continued, a degeneration of the protoplasmic processes of the cells of the cortical gray matter. Their irritability being thus decreased, and their power of discharge diminished, we would expect the paroxysms to be less in number and severity, if not absent, until those cells regain their former tone, when the paroxysms return. Is that not clinical experience? In some cases the bromides act better when salt is withdrawn from the food. A combination of bromides, with increasing doses of opium, is the latest recommended specific. In Meyer and Wickel's report, I would call special attention to the dietary and hydrotherapy to which no doubt much of their success is due; and the treatment will succeed in a limited number of cases, provided the habits of the patient are proper after the treatment has ceased.

The bromides, however, have the power to moderate the congestion, whatever may be the cause and wherever the location (Féré), and they are useful in all cases in just sufficient quantity to reduce the central irritability until the cause can be affected. To a patient with petit mal who had three paroxysms while consulting me, I gave twenty-grain doses of equal parts of bromides of potassium, sodium, and ammonium for two weeks, twice a day, and with attention to digestion, the use of laxatives, etc., and daily cold baths, there was no paroxysm for six months, while my instructions were being followed. As to which of the bromides should be used, it will be found that one salt or combination will give best results with one patient while another will act better on another. The action on the patient should decide this, though some favorite remedy is usually the one given.

Instead of depressing the system generally, the most perfect performance of functions of every organ and cell in the body should be secured, by organic stimulants, tonics, adjuvants, or correctives.

Digitalis has long been considered a valuable remedy in connection with bromides. Some believe it to have a specific effect on the central nerve cells, but further observation will probably show us that this drug affects epilepsy to just the extent that the disturbances of the kidneys, heart, or blood vessels enter as causal factors. The same may be said of adonis vernalis, nitroglycerin, and belladonna in accordance with their physiological action. Strychnine is of great value in debility (Peterson); arsenic and iron in anæmia. Gowers mentions cases cured by the administration of iron along with bromides.

The exhibition of digestive ferments and tonics to correct digestion along with proper diet is essential in the treatment of many cases. The much-lauded borax seems to me to be but a mild antiseptic and may be advantageously replaced by resorcin, salol, or β-napthol. Undoubtedly an occasional

course of some intestinal antiseptic will have a favorable influence in a great number of cases (Herter and Smith). My attention was first called to this fact by the administration to a confirmed epileptic of salol at intervals for three or four months. The disease under treatment being relieved, the patient was dismissed, but returned in a few days, saying he wanted more of the same medicine as he had had no "fits" since he began taking it. I have seen sufficiently good results in other instances to convince me of its value in selected cases. Intestinal antiseptics counteract greatly the incidental effects of the bromides (Féré). Intestinal parasites must be removed and the bowels kept clear by laxatives. An occasional dose of calomel is indispensable, since it not only clears the alimentary tract, but stimulates every gland connected with it. Finally, it must be said that epilepsy is too complex a disease to have a specific—the goal at which nearly all observers seem to aim, who, having found a remedy for a few cases, announce to the world a specific for the disorder. Each case should be considered by itself and be treated on its own merits.

Treatment of the Paroxysm.—The patient must learn to avoid anything that will bring on the paroxysm, and all places when there would be danger should a paroxysm occur. If the aura consists of some mental vision, an effort should be made to keep the mind from that subject (Gowers). Emetics during the aura will in some cases prevent the paroxysm. When the spasm begins in the extremities and extends over the body it may sometimes be checked by constriction above the part already affected. Inhalations of amyl nitrite, chloroform, or ether are useful in certain cases in aborting the spasm.

At the beginning of the spasm the patient should be placed in a reclining position so that no injury is sustained from a fall. Dislocation of the joints is quite a troublesome complication in some cases. The head should be extended and turned to one side to prevent the tongue from falling back into the throat and causing suffocation during the sterterous period. A cork or some similar body may well be slipped between the teeth to prevent biting of the tongue. If the attacks come on during the night the patient should be watched, since there are numerous instances of asphyxiation resulting from burying the face in the pillow. The sleep following the attack should be undisturbed, the patient being placed on a comfortable bed or couch.

During psychic seizures, good results may be obtained from agents directed toward lowering arterial tension, such as the mustard bath or atropine, or pilocarpine hypodermically. In the status epilepticus, the patient must be removed from all noise and excitement, best to a dark room. When he arouses he should speak very little if at all. He should be systematically fed, if necessary through a stomach tube (Féré). A lowering of blood pressure is also indicated here, and the above remedies will do well. In either case, the bromides are to be used as nervous sedatives.

In general practice, it is very difficult to treat the average epileptic, since it is practically impossible to control his habits and diet and give him sufficiently careful attention outside of an asylum or home. However enthusiastic your patient may be and desirous of relief, and even if success attends the first weeks of treatment, as months go by the enthusiasm wanes, and he returns to his old habits. The patient with petit mal referred to above was forbidden to eat meat, and although he had had no paroxysm for six months he came at the end of that time and said "he would rather eat meat and have fits," and he did both.

The treatment can, therefore, be satisfactorily given only in homes for epileptics, of which we have a number in New York, Pennsylvania, Ohio, and other States; but few of them provide medical attention for the malady for which they were established. Let us hope that the treatment of this disease will soon be on a strictly scientific basis, and that there will be a home or colony, rather than a hospital, open to every epileptic, where he can enjoy life, earn a living, and at the same time receive the proper medical attention.

Constipation in Infancy and Early Childhood.—According to J. M. Dunham, the causes of constipation in the earlier years of life can all be grouped under three general heads—a decrease in the secretion of the intestinal glands and the liver, muscular atony, and unsuitable diet. Hence, any rational treatment must begin with the removal of the exciting cause. Infants and young children should never be allowed to retire at night without having had a movement of the bowels. The second fact to be insisted on is a proper diet. Infants fed upon cow's milk usually receive, when diluted, one part cow's milk to one of water. This ordinarily means 2 per cent. fat and 2 per cent. casein, while the proper amount for an infant is 2 to 3 per cent. fat and 1 to 1.5 per cent. casein. Children in the second year require still different proportions of fat and casein. When they are suffering from constipation, cream and water should be added to the milk, so that they receive 4 per cent. fat and 3 per cent. casein. One usually finds children who have constipation partake very freely of starchy foods. If these are supplanted by beef juice and other meat juices, the salty constituents of these will help to overcome the habit of constipation. Fruits are usually of considerable service. Many drugs have been used to overcome the trouble under consideration. Many cases will yield readily to the use of powdered rhubarb and magnesia in teaspoonful doses. The aromatic syrup of rhubarb is also very good. In atonic conditions of the bowels, in doses of $\frac{1}{150}$ grain, strychnia sulphate twice a day is very good. The most satisfactory drug in my experience has been the fluid extract of cascara sagrada, used in the proper manner.—*Columbus Medical Journal.*

An Obstinate Surgical Case Treated by Koch's Tuberculin.—J. Ramsay reports the case of a man suffering from abscesses of the shoulder, swelling and pain of the knee-joint, and pain and swelling of the right side of the head. The shoulder condition was undoubtedly tuberculous, the cranial condition and the right knee probably so. Surgical treatment did not relieve. Injections of Koch's tuberculin (the "old form," not the more recent material) were commenced May 10, .05 m. being given daily, increased to .12 m. by June 1, and to .17 m. by June 19. Early in July the ulcer had soundly healed, and the patient was having m. ii. tuberculin injected daily. This dose was then given on alternate days for a fortnight, and on July 19 he had his last dose. The shoulder scar was sound; there was no pain; there was no swelling on the head; the knee was quiescent, and he was wearing a plaster-splint. September 3 he was discharged. The marked improvement dated from the time of the use of the tuberculin, and that at a bad time of the year. It was interesting to note how the reaction could only be induced by gradually increasing the dose, or by intermitting the larger doses.—*Intercolonial Medical Journal of Australasia.*

"Family" Diabetes with Sclerosis of the Pancreas.—R. Silvestrini and G. Nesti report the case of a man who died of diabetes, of which disease a brother, also, had died. The course of the disease was rapid, and classic in type. No symptom (excepting glycosuria) attracted

any attention to the pancreas. Histological examination, however, showed interstitial, intralobular, and interacinous pancreatitis with sclerosis, and almost total destruction of the pancreatic islands. It appears to be certain that there is some connection between some forms of pancreatitis and certain forms of diabetes. The special resistance of the islands of Langerhans in some morbid processes of the pancreas, and the localization of other morbid processes in them, together with the coincidence of their destruction in glycosuria, seem to indicate that they possess individuality and special functioning powers. But whether they are organs of secretion, as Languesse holds, or elaborate the glycolytic ferment, as Lepine asserts, or the substance which Chauveau and Kaufmann consider to possess a regulating power over the production of sugar of the liver, it is impossible to say.—*Rivista Critica di Clinica Medica.*

Acid-fast Bacilli in Gangrene.—Alberto Folli writes of a pseudo-tubercular bacillus whose presence under certain conditions may cause diagnostic errors. Frankel, Pappenheim, Rabinowitsch, and others have found these bacilli in cases of pulmonary gangrene. Laabs found them in deposits on the teeth, Möller in the sputum in a case of simple bronchial catarrh, Dietrich in a suppurating ovarian cyst, Karlinski in the nasal secretion in a case of tertiary syphilis. The writer himself found them a few years ago in the sputum of a youth who died presumably from tuberculosis. At the autopsy, gangrene of the lung was found, but no trace of tuberculosis. He reports three recent cases of grangrene in which acid-resisting pseudo-tubercular bacilli were found. The bacilli were not alike in every case, but were alike in resisting the decolorizing power of acids. The author does not deny the possibility of a cure in tuberculosis, but he thinks that in many cases diagnosed as such, the presence of these bacilli may have led to error.—*La Riforma Medica.*

Irradiations and Sensory Reflexes of the Sympathetic Nerve.—Max Buch holds that these irradiations and reflexes do not need to travel through the spinal cord or brain, but are produced through the agency of sympathetic ganglia, as in the case of motor and secretory reflexes. This opinion is confirmed by the fact that the radiations often occur in several directions, which would be difficult to understand were it not supposable that several hyperesthetic ganglia were irritated at the locality affected, and communicated this irritation to the brain; and by the fact that pain is often felt, not only at the source of the irradiation, but all along its course; as, for instance, from the superior hypogastric plexus, along the median line of the abdomen and thorax, up to the neck. The latter occurrence can be explained only on the supposition that the sympathetic nerve itself conducts the impulses. The sensory cerebrospinal nerves are largely composed of fibers of the sympathetic.—*Finska Läkaresällskapets Handlingar.*

Surgical Intervention in Cirrhosis of the Liver, with Especial Reference to Ligature of the Portal Vein and the Inferior Vena Cava.—G. Pascale holds that this method of relieving the impeded circulation in the branches of the vena cava by grafting of the gastroepiploic, development of the collateral cutaneous circulation, and anastomoses with the capillaries of the vena cava is rational and useful. It does not cure cirrhosis, but it relieves the obstructed circulation, and delays the alteration of the hepatitis cells. It induces a compensation for the ascites by creating better hydraulic conditions, by improving the perihepatics and chronic peritonitis, and the tonicity of the blood vessels. It increases the amount of urination from 200 to 800 gr. up to 2 liters a day. It increases the amount of urea excreted, and diminishes the uroerythrin. It also improves the general condition, as the patients increase in weight and in fat. The process is not equally successful in all cases, however.—*La Riforma Medica.*

Prolonged Septicæmic Infection.—F. V. Milward reports the case of a primipara suffering from a mammary abscess developing about a month after confinement. The case ran on to a septicæmic condition, finally terminating in pyæmia, the immediate cause of death being a pneumonia which did not appear until nearly six months after confinement. It was difficult to determine the origin of the sepsis, as the mammary abscess healed completely, and a subsequent blood-test did not reveal the characteristic pus-reaction. The microorganism found in the pulmonary deposits seemed to be of a low grade of virulence. Serum-injections were tried without avail, and various blood-counts made during the later stages of the case did not appear to throw any light upon what was finally determined to be the true condition.—*Birmingham Medical Review.*

The Liberation of Nascent Iodine in the Lungs as a Therapeutic Measure.—From a series of experiments conducted on the lungs of animals, A. Cavazzani and O. Spadoni conclude that the iodide of potassium can be decomposed in the lungs by means of insufflations of the vapor of turpentine, and that the nascent iodine thus liberated immediately forms new combinations with the organic elements which it meets. It is therefore logical to infer that in the treatment of pulmonary affections by means of the administration of preparations of iodine and turpentine inhalations, the favorable results are in part due to the development of nascent iodine in the affected tissues. Further researches are under way to ascertain whether iodine has more affinity for diseased pulmonary tissues in general, and tuberculous tissues in special, than for healthy tissues.—*La Riforma Medica.*

Clinical and Anatomico-Pathological Study of a Case of Chorea Minor.—Vincenzo Scarpini concludes from his study of this and other cases, that when chorea is the only cause of death, the post-mortem findings are not such as to explain the pathogenesis and the fatal issue. The clinical type of these cases consists in a rapid course, notable pyrexia, hallucinations and maniacal delirium, convulsions, and coma. The author thinks that it may be a special disease as yet unknown, and caused by the same infection as chorea. He is pursuing researches which point to the existence of functional chereas, caused by various microorganisms, with the prevalence of the common pyogenes. Among these is a rare form, whose typical course suggests the thought that it may be found to merit a place of its own in the chapter of neuropathies.—*La Riforma Medica.*

Subcutaneous Fracture of the Larynx.—Antenore Nizzoli reports a case of this rare lesion in a child of ten years, who fell heavily from a bicycle, striking his throat on the handle. Pain, aphonia, attacks of suffocation, and the raising of mucus and blood followed. Examination showed fracture of the larynx. Tracheotomy was refused by the family, and treatment consisted in immobilization of the head with extended neck, an ice bladder around the throat, and prohibition of solid food. Little by little, all symptoms improved, a little milk was given on the first, but no solid food until the seventh day. On the tenth day recovery was complete, a deviated Adam's apple and hoarseness being all that remained to testify to the grave injury received.—*La Riforma Medica.*

Appendicitis, and Abnormal Forms of Typhoid Fever.—Professor Zagari concludes that typhoid may be masked by the symptoms of appendicitis, and that circumscribed peritonitis of the ileocecal fossa is essential to the syndrome of appendicitis. In addition to the usual etiological factors of appendicitis (coli bacillary infection, calculus, foreign substances, etc.), to tuberculosis, and peritoneal neoplasms we must add typhoid fever. Before deciding upon operative measures in appendicitis, it will be well to exclude typhoid infection.—*La Riforma Medica.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, October 12, 1901.

THE YELLOW FEVER INSTITUTE OF THE MARINE HOSPITAL SERVICE.

THE most remarkable feature in the steps taken by Science to release the human race from the grip of disease, during the past twenty years, has been the successful discoveries made in the field of bacteriology. Investigation has laid bare the cause of tuberculosis, of diphtheria, to name but two of the maladies of which the secrets have been wrested, by the genius of man, and by painstaking research, and while the studies dealing with the cure of disease have not yielded like brilliant results, yet enough has been accomplished to justify the hope that much more may be attained in this direction, in the time to come.

The lesson, however, taught by recent researches would seem to be that the treatment of disease in the future will tend rather to prevention than cure. The work of such men as Koch, Laveran, Ross, and others has given an immense impetus to original research, and has convinced those nations which have hitherto neglected this branch of science that, if they wish to be in the van of progress, they must gird up their loins, and resolve to grudge neither pains nor money to reach this proud position.

The United States has been in the past, undoubtedly, one of the countries to miss her opportunities in this respect. Happily, there are signs that these sins of omission are to be atoned for, and the dawn of a new era for science may be looked for in America.

The investigations of the Medical Commission of the United States Army, with regard to yellow fever, as is well known, have met with a most satisfactory termination. The rôle of the mosquito in conveying this disease, according to the Commission's report, has been definitely decided, and the particular mosquito which alone is able to transmit the malady to man has been confidently isolated. The conclusion is also that the cause of the disease is unknown.

The medical and lay journals of this country have, within the past few years, devoted a considerable amount of time and space to a consideration of yellow fever in all its aspects, and especially have the investigations conducted in Cuba been followed with the greatest amount of interest by the medical profession and the general public.

The attitude of medical men in the United States with regard to the emphatic assertion of the United States Army's Commission, that the mosquito stegomyia fasciata is the sole agency whereby yellow fever can be conveyed to the human race, has been distinguished for the most part by a judicious impartiality. Perhaps the majority have accepted, without reserve, the findings of the Commission, and have acknowledged that the case against the mosquito has been proven once and for all. Nevertheless, there are still some investigators, who, while freely admitting that the work of the Commission has gone far toward settling the question, are yet of the opinion that the final solution will not be reached until some moot points have been elucidated.

Among this conservative band must be placed Surgeon-General Wyman, and the members of the United States Marine Hospital Service, who have labored long and ably to discover the cause and prevent the spread of yellow fever.

Since the report of the Army Commission has been published, the Marine Hospital Service has especially prosecuted its investigations, with reference to the findings of the Commission, both in the hygienic laboratory and by special orders transmitted to the officers assigned to the several fruit ports of Central America, to the medical officers in Cuba and Porto Rico, and to those at the Southern quarantine stations of the United States. Notwithstanding this activity, General Wyman has become alive to the fact that the work can be carried on in a more effective manner if the methods now in vogue are systematized, and consequently he has organized and established a yellow-fever institute in connection with the Marine Hospital Service. The members of this institute are to be the medical officers of the United States Marine Hospital Service, and others specially qualified. Each of the four sections will be under the direction of one of the medical officers on duty in the Marine Hospital Service Bureau; and said bureau officers, with the director of the hygienic laboratory, the Surgeon-General, and a Secretary, will constitute an executive board, which is to have general oversight of all the investigations.

The different sections into which the work of investigating is divided are as follows: History and Statics, Etiology, Transmission, Quarantine and Treatment. The topics considered in the transmission of yellow fever are: The transmission of the disease by the mosquito. Can any other mosquito than the stegomyia fasciata carry the infection? Is the progeny of the mosquito also infected? How many generations? Can the mosquito become infected by any other means than by sucking the blood of a patient sick with the disease? Can the mosquito become infected by contact with the dried-blood discharges or other infected materials upon fomites? Can the disease be transmitted by any other means than through the mosquito? Can the disease be conveyed by fomites, or through the air, soil or water? The geographical distribution of stegomyia fasciata in relation to the disease. Is the immunity enjoyed by certain localities due to the absence of this variety of mosquito? A study of the life and habits of stegomyia and allied species, especially with a view to their extermination.

These topics cover the whole ground, and their correct interpretation will provide the ultimate answer to the question of the transmission of yellow fever.

The organization of the institute reflects great

credit upon its projector, the admission of outside contributors, by invitation, being a particularly happy thought.

The move is assuredly one in the right direction; yellow fever is peculiarly the disease of this portion of the world, and it is fitting that to American scientific men should belong the honor of discovering its unsolved features, and of ridding the race of the scourge. Moreover, if General Wyman's scheme with regard to yellow fever prove successful, it will not only be the means of stimulating healthy emulation among American investigators, but will also pave the way for the establishment of similar institutions for the investigation of other important diseases.

The action of Congress in providing the necessary funds to conduct the work of the institute is a noteworthy and significant manifestation of the trend of public opinion. It is palpable, even to the comprehension of the man in the street, and the fact has been emphasized many times in the MEDICAL RECORD, that, if America or any other country is desirous of leading in matters scientific and incidentally in successfully fighting disease, the State must be open handed in supplying the sinews of war. By such means, Germany leads at the present time, but the United States with her superabundant riches should, in the course of a few years, be able to challenge this supremacy.

CONGRESS OF CRIMINOLOGY AT AMSTERDAM.

THE Fifth Congress of Criminal Anthropology was held in Amsterdam during the second week of September. It was largely attended, most of the prominent professors of the science being present. The star of the meeting was Professor Cesar Lombroso, who spoke at some length. In concluding his speech as reported in the New York *Tribune*, Lombroso brought up the subject of the remedies to be applied to the natural-born criminal.

Upon the second day of the meeting, as usually happens when they come together, the partisans and opponents of the Italian School clashed, MM. Garnier and Crocq championing the cause of those who believe that criminality is as often the result of accidental circumstances as of physical degeneration. M. Garnier said that statistics amply prove that the increase of crime among youths and girls was greater than among adults.

There are six times as many murders committed by persons, between the ages of sixteen and twenty, as by adults between thirty and thirty-five. This fact is attributed to the progress of alcoholism. The study of the etiology of crime should lead legislators to take hygienic measures against alcoholism.

Miss Robinowitch of New York made, perhaps, the most sensible proposal of any of the speakers; when protesting against the prevailing system of giving all school children a uniform education, without any regard to other conditions, she declared that a selection should be made among children and appropriate courses of instruction given to every category of physical beings.

The recent assassination of President McKinley has once again thoroughly aroused the attention of the civilized world to that part of the human race generally known as criminal degenerates, and has impressed upon the minds of those in authority the absolute necessity of grappling with the problem of how best to deal with them in a manner at once practical, prompt, and satisfactory.

The study of criminal anthropology, and of the means whereby to fight the individual of criminal proclivities, whether inherited or developed, will be perhaps found to be the most efficacious mode of freeing society from the curse of anarchy. This country at present is far behind Europe in matters relating to psychical research a reproach which it is hoped will be soon removed.

IODOPHILIA.

THE diagnosis of pneumonia at an early stage and of so-called central pneumonia at any stage is often a matter of no little difficulty, and it would naturally be a great gain to possess a ready and reliable means of recognition when the usual physical signs and symptoms are wanting. Such an expedient, it would appear, is to be found in the demonstration in the blood of leucocytes that exhibit a peculiar reaction to iodine and for which reason the name iodophilia has been given to it by Dr. Theodore Dunham (*Boston Medical and Surgical Journal*). The reaction, it is true, is not exclusive to pneumonia, occurring also in the presence of suppuration and of some other disorders, which, however, are readily recognizable by other means. Nevertheless, it may prove to be a useful aid in diagnosis. The reaction is developed by exposing a spontaneously dried blood-smear to the action of a solution containing three parts of potassium iodide and one part of iodine in one hundred parts of water, brought up to a syrupy consistency by the addition of lumps of gum arabic. Normally the lymphocytes and the eosinophile cells are not affected by the stain, while the polymorphonuclear neutrophiles either are unaffected or their protoplasm is tinged a faint pinkish or brownish color. Under some pathological conditions, however, the protoplasm of a certain proportion of the polymorphonuclear neutrophiles takes on a reddish-brown color, which in some is diffuse, in others forming a granular network, in still others appearing in large or small refractive granules varying from a light pink to a dark red. The condition seems to occur always in the presence of progressive suppuration and of progressive pneumonia and also of a few other morbid conditions. The intensity of the reaction seems to be closely related to the intensity of the suppurative process. The special value of the reaction in cases of pneumonia resides in the fact that it occurs before physical or other specially suggestive signs make their appearance. Iodophilia has been observed also in cases of various forms of profound blood-change, but these are not likely to be confounded with pneumonia.

SYPHILITIC FEVER.

SYPHILIS, like hysteria, appears in many guises, and unless one be constantly on his guard he is likely every now and then to suffer the mortification of mistake. The liability to error is augmented by reason of the long period of time covered by the disease, as well as by the protracted periods of latency, in which respect it differs radically from most other infectious diseases. Like the latter, however,

syphilis is attended with febrile elevations of temperature, the significance of which may be unappreciated even when other evidences of the disease are obvious, while the difficulty is immeasurably greater when such evidence is wanting. It should therefore be the rule in any case of obscure febrile character to look for signs of syphilis, such as periosteal thickening or visceral lesions. Any doubt which may exist will be cleared up by the results of antisyphilitic medication. In a recent communication, T. B. Futcher (New York *Medical Journal*, June 22, 1901) discusses syphilitic fever in an interesting manner and cites a number of illustrative cases. He points out that the symptom may appear a longer or shorter time before, or even coincidently with, the secondary cutaneous eruption or at any time during the course of the secondary or the tertiary stage. The fever is sometimes mild and continued, at other times remittent, and at still other times intermittent, and it is often preceded by a chill and followed by sweating. It may thus simulate typhoid or malarial fever, tuberculosis, rheumatism, or septic infection. Examination of the blood for the Gruber-Widal reaction and for the presence of malarial plasmodia and of bacteria, of the stools for typhoid bacilli, and of the sputa for tubercle bacilli, and finally the application of the therapeutic test, in addition to search for collateral physical signs, may, under such circumstances, be necessary to establish the diagnosis.

THE QUESTION OF FEEDING IN CASES OF DIPHTHERIA.

THE administration of nourishment in the presence of acute disease, particularly in children, and more especially when food cannot for any reason be taken in the usual way, becomes at times a matter for most serious consideration. This problem not rarely presents itself for solution in cases of diphtheria, though by no means with the same frequency now as prior to the general employment of antitoxin. Under ordinary circumstances feeding by the mouth is to be preferred over all other methods, and milk will naturally constitute the principal article of food. Swallowing may, however, be rendered impossible on account of pain or faucial swelling, or regurgitation or vomiting may take place, or food gains entrance into the larynx in spite of every precaution, or attempts at feeding are attended with such struggling as to cause exhaustion. In the presence of any of these conditions some expedient must be resorted to to take the place of the usual method of administering food. Among the substitutes for mouth feeding are nasal feeding through a tube, rectal alimentation, and subcutaneous injection of sterile horse-serum. The indications for these are briefly discussed by R. G. Kirton in the *Lancet* of June 15, 1901. For nasal feeding a soft rubber tube is commonly employed, although occasionally a stiff tube becomes necessary. The food should be liquid, strained, warm, and administered in small quantities at intervals of four hours. Rectal feeding will have to be resorted to when mouth-feeding or nasal feeding does not meet the requirements of the case. A funnel and a rubber tube may be used for the purpose, the latter being introduced as high up into the rectum as possible. Here also the food should be liquid, strained, warmed, and administered in small amounts at intervals of four hours. When a sufficient quantity of food cannot be administered by the mouth, through the nasal tube, or by way of the rectum, recourse may be had to subcutaneous injection of sterile horse-serum, from twenty to forty c.c. being thrown daily into the loose subcutaneous tissues of the trunk.

THE HEALTH OF THE KING OF ENGLAND.

THE newspapers in Copenhagen, a place where many rumors concerning royalty emanate, recently received the reports that King Edward is suffering from cancer of the tongue. A despatch from London also says that a story is in circulation among the clubs, purporting to come from a titled member of the late Queen Victoria's household, giving color to the cancer story and saying that court circles are discussing the possibility of no coronation next year. It is said also that he has been undergoing local treatment of the throat by spraying for several months. The MEDICAL RECORD is pleased to state, however, that it received, as late as Wednesday of this week, from a most trustworthy source, the following cablegram: "The King is and has been quite well."

It is safe, then, to assume that the cancer story is a myth, as are all other accounts of his failing health.

News of the Week.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending October 5, 1901:

	Cases.	Deaths.
Measles	48	6
Diphtheria and croup	181	31
Scarlet fever	85	5
Smallpox	7	2
Chickenpox	6	..
Tuberculosis	225	134
Typhoid fever	143	15
Cerebrospinal meningitis	..	0

The Medical Society of the County of New York will give a reception to the Medical Society of the State of New York, at the Academy of Medicine, on the evening of Wednesday, October 16. Personal invitations will not be sent out, but it is hoped that as many members as possible will be present.

A McKinley Memorial.—It is proposed by Dr. S. A. Knopf of this city that a seaside sanatorium, with a pavilion for every State, for the treatment of American children suffering from tuberculous and scrofulous diseases, or predisposed to consumption, be established in memory of our lamented late President. The idea is an excellent one, and should forcibly appeal to the charitable public.

A Bill for Professional Services.—A Pittsburg physician has put in a bill of $5,240 against the estate of a deceased millionaire for professional services during a period of five months. His charges were $25 each for visits at his patient's residence, and $100 a day for accompanying him on a three weeks' visit to Atlantic City.

Vaccination of Italians.—The Board of Health of this city has made the suggestion to employers of Italian laborers that they demand as a requisite to employment the possession of a certificate of vaccination. Many cases of smallpox occur among

Italians, and the health officials say that persons of this nationality will not voluntarily submit to vaccination, and so are often instrumental in spreading the disease.

University of Pennsylvania.—Dr. M. Howard Fussell has been elected Assistant Professor of Medicine. Dr. Thos. R. Neilson, Assistant Clinical Professor of Genito-Urinary Diseases, and Dr. Elisha H. Gregory, Jr., Demonstrator of Anatomy. Dr. H. C. Wood has resigned as Clinical Professor of Nervous Diseases, but remains Professor of Materia Medica, Pharmacy, and General Therapeutics, although he has been granted leave of absence for one year on account of impaired health. In his absence, Dr. F. A. Packard will deliver the lectures on "Applied Therapeutics," and Dr. H. C. Wood, Jr., the lectures on "The Physiological Action of Drugs."

A Systematic Study of Yellow Fever is about to be undertaken by the Marine Hospital Service, the incentive thereto being the discoveries made by the army medical officers in Cuba, and the demands, based upon these discoveries, made in the interests of commerce for a relaxation of the existing quarantine regulations. For the better carrying out of the desired investigations, an institute will be established for the purpose of collecting all facts concerning yellow fever, to designate the specific lines of inquiries to be made, and to make the same. The work will be divided among four sections, on history and statistics, etiology, transmission, and quarantine and treatment, respectively. The following are the topics to be considered by each of the sections:

A. History and Statistics: 1. The early history of the disease. 2. Relation to the slave trade. 3. History of recent epidemics (since 1850). 4. Relation to modern sanitation, especially paving, drainage, etc., in cities. 5. Why did not New Orleans have it in early times while Boston did? 6. Mortality statistics. 7. Maps showing yellow-fever zones. 8. Maps showing the infectible territory in the United States.

B. Etiology: 1. The cause of the disease.

C. Transmission: 1. The transmission of the disease by the mosquito. 2. Can any other mosquito than the stegomyia fasciata carry the infection? 3. Is the progeny of the mosquito also infected? 4. How many generations? 5. Can the mosquito become infected by any other means than by sucking the blood of a patient sick with the disease? 6. Can the mosquito become infected by contact with the dried-blood discharges or other infected materials upon fomites? 7. Can the disease be transmitted by any other means than through the mosquito? 8. Can the disease be conveyed by fomites, or through the air, soil, or water? 9. The geographical distribution of stegomyia fasciata in relation to the disease. 10. Is the immunity enjoyed by certain localities due to the absence of this variety of mosquito? 11. A study of the life and habits of the stegomyia and allied species, especially with a view to their extermination.

D. Quarantine and Treatment: 1. Is disinfection of baggage necessary to prevent the spread of the disease? 2. Is any treatment of baggage necessary? 3. Mosquitos in baggage, in merchandise, in cars, in ships. 4. Treatment of the patient. 5. Guards against mosquito bites. 6. Immunity of individuals, of races. 7. Individual prophylaxis. 8. Communal prophylaxis—sanitation.

Officers of the State Board of Dental Examiners.—At the annual meeting of the New York State Board of Dental Examiners, held October 5, at the Regents' office, Albany, the following officers were elected for the present academic year: *President*, Dr. S. B. Palmer of Syracuse; *Secretary*, Dr. Frank French of Rochester; *Editor*, Dr. William Carr of New York.

A Request for Better Wages at Bellevue Hospital.—The New York City Board of Apportionment recently received from the State Charities Aid Association a request for larger salaries in the lower grade of service in Bellevue Hospital, where the female helpers now receive only $12 a month. If better wages were paid and better living quarters provided, the association urged, Bellevue would have as good service as is now had at the first-class private hospitals in the city.

Losses in the British Army in South Africa.—The latest official report, issued a week ago in London, states that the British casualties in South Africa, from the beginning of the war to September 30, were 548 officers and 5,823 men killed in action, and 1,529 officers and 28,632 men wounded; 365 officers and 9,177 men are classified as missing or prisoners, of whom 354 officers and 8,471 men have either been released or have escaped. The deaths from disease and accidents numbered 10,738.

Veterinary Surgeons Needed in the Public Services.—Complaint is made of great difficulty in getting veterinarians qualified to do the work of food and animal inspection for the Bureau of Animal Industry in the Agricultural Department. One reason alleged for this scarcity is that the British government has been a large purchaser of horses and mules for use in the Boer war, and has employed many veterinarians at good salaries to see that the horses purchased were sound.

Rabies in Pennsylvania.—One of the hounds of the West Chester (Pa.) Hunt developed hydrophobia a few days ago, and bit thirty-five other dogs in the kennel. The dog is known to have been suffering from genuine rabies, and it is believed every one of the bitten hounds will have to be killed.

A Conference of Sanitary Officers of the State of New York will be held at Albany on October 24 and 25. It will commence with an evening session on the 24th, which will be held in the Assembly Chamber of the Capitol, and it is expected that the meeting will be addressed by Governor Odell. The next day, there will be a morning and afternoon session, and the conference will close with a banquet in the evening at the Hotel Ten Eyck. The object of this gathering is to afford an opportunity for meeting and making the personal acquaintance of the local and the central health authorities, and in a personal conference to present, by addresses and discussions, subjects and matters which are of practical and immediate interest to boards of health and their executive officers. The discussion of practical sanitary matters is one of the chief objects of the conference, and topics for this are chosen in which, in the advisory capacity of the central department, it has been found that the executive officers of the local boards have asked for assistance. More general subjects also will be discussed, and those which are in the way of future work in sanitary affairs that are opening up for health boards in general or those which for many local boards are soon to demand attention. A partial program of the meeting, which has been prepared and is being sent out, includes the following topics: "Testing the Eyes of School Children," by Dr. P. A. Callan of the New York Eye and Ear Infirmary; "Sewage Disposal for Cities and Villages," by Professor O. H. Landreth, School of Engineering, Union College, and further discussed by J. J. R. Croes, President of the American Society of Civil Engineers; "The Attitude of Health Officers Toward Tuberculosis in the Smaller Cities and Towns,"

by Professor Hermann M. Biggs of the Health Department of the City of New York; "Milk Supply of Cities and Villages," by Dr. Ernest Wende, Health Commissioner of Buffalo; "Some Essentials of a Registration System," by Professor Walter F. Willcox of the U. S. Census Office; "The Diagnosis of the Exanthemata," by Dr. F. C. Curtis, Professor of Dermatology in the Albany Medical College. The new Serum Laboratory and the Bureau of Pathology will be described by Dr. H. D. Pease and Dr. George Blumer, who are in charge of these new departments. There will also be an exhibition of disinfecting apparatus and their use demonstrated. Sanitary conventions have been held in other States, but this is the first general meeting of this sort which has been called together by the State Department of Health of this State in its twenty years of existence. The Commissioner of Health purposes to have such a meeting annually hereafter if the response to the present invitation and the attendance upon it are such as to warrant it in the future.

Opposition to Women Medical Students in Germany.—The professors of anatomy, chemistry, and physics at the University of Konigsberg have excluded women students from their lectures, with the result that women cannot study medicine regularly at that institution.

Dr. W. D. Shelby, Captain and Assistant Surgeon of the United States Army in the Philippines, has given Hanover (Ind.) College a fund, from the proceeds of which a medal will be struck annually for the best work in scientific studies.

Advance of the Plague.—Reports to the Marine Hospital Service from all parts of the world show a continued spread of the plague. In British East India, during the week ended August 2 last, 2,622 new plague cases were reported and 1,930 deaths were recorded in the Bombay presidency, an increase of more than 200 deaths over the previous week. There were 136 plague deaths in the city of Bombay that week, and many others suspected. In Egypt, the total number of bubonic-plague cases from April 7 to September 2 was 132, with 60 deaths. In Queensland the destruction of rats continues, but the official report shows thirty-two plague cases, including ten deaths from February 28 to July 6. In China, at the port and town of Swatau and neighboring districts, the plague is steadily decreasing.

Legal Decision on a Question of Pathology.—A man in Rochester who suffered from ivy poisoning, which confined him to the house for three weeks, made a claim against an accident insurance company for compensation. The company alleged that the man was not wholly disabled, and that, even if he were, he could not recover more than one-tenth, by reason of the provisions set forth in the face of the policy, in which it is held that for any poison absorbed or inhaled the company's liability shall be one-tenth of what it would otherwise be. Regarding the question of total disability, the court decided that a man whose features were so distorted that he was unrecognizable, and who suffered pain and irritation in the skin from the effects of the rhus poison, was plainly suffering from total disability. On the second point the judge sustained the answer of the company. He said that "there was no proof that the contact with the plant was violent, within the meaning of that word. Violence imports something more than a mere touch. It means great physical force. Nothing of that kind occurred here. The plaintiff's body came in contact with a poisonous plant, and the pores of his skin sucked in or absorbed the virus exuding from the leaves. This is just what occurred, nothing more nor less." And on the strength of this belief he decided that the sufferer could claim only one-tenth of the amount which would have been due him for total disability resulting from actual violence.

An Irate "Coverer."—A "medical institute" in this city employed a registered physician to act for it when any inquisitive person questioned the legality of its therapeutic efforts. A few days ago, the coverer's wages were withheld for some reason, and this aroused his ire to such a degree that he seized a hammer and broke every mirror, every piece of furniture, and all the bric-à-brac in the office of the concern. The police were called in, the angry man was locked up, and the treasurer of the company is on the lookout for a new medical sponsor for the concern.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the Medical Corps of the Navy, week ending October 5, 1901: September 30—Surgeon P. Leach, ordered to recruiting duty at Port Royal, S. C. October 1—Surgeon P. Leach, order to recruiting duty at Port Royal, S. C., revoked. October 2—Assistant Surgeon E. J. Grow, order to proceed home, upon detachment from the *Castine*, modified; ordered to the New York Navy Yard. October 3—Medical Director J. C. Ayers, detached from the Naval Hospital, Chelsea, Mass., October 15, and ordered home and to wait orders. Medical Director D. Dickinson, detached from duty on medical examining board at Washington, D. C., October 10, and ordered to duty in charge of the Naval Hospital, Chelsea, Mass., October 15. Surgeon S. H. Griffith, detached from duty at the Pan-American Exposition, Buffalo, N. Y., October 9, and ordered to duty as a member of the medical examining board, Washington, October 10. Surgeon H. L. Law, retired, ordered to duty at Buffalo, N. Y., in charge of the exhibit of the Bureau of Medicine and Surgery at the Pan-American Exposition, and as attending medical officer at the naval recruiting rendezvous, October 9. Assistant Surgeon D. B Kerr, detached from the *Culgoa*, when put out of commission, and ordered home and to wait orders.

A Strange Proceeding in St. Louis.—Dr. Louis Knapp of St. Louis has been, at his own request, shut up with a Chinese leper in the isolation hospital, and will there remain, so the newspapers announce, until the man dies. The leprosy hospital is a frame cottage of three rooms, within sight of the smallpox station. The middle room is the kitchen, and the other two are for the doctor and leper. The food and such other articles as may be daily needed will be placed under a temporary shelter half-way between the smallpox station and the leper ward by an attendant, and later taken to his quarters by Dr. Knapp, where he will prepare the food for himself and patient. The physician is said to have left a wife and family to live on his salary of $50 a month, while he has immured himself with this leper in order to study his disease. The health commissioner, it is said, though one can scarcely believe it, insisted upon this complete and absolute isolation, through fear of the spread of the disease to others were the medical attendant permitted to visit his family after having been with the leper. It is strange that an educated physician should be willing to make such a sacrifice for the sake of studying a disease which he could study just as well elsewhere, without deserting his family, especially as the probabilities are that he will learn nothing that is not already known and contained in every modern work on leprosy. It is strange, also, that a health com-

missioner, in the year 1901, should look upon the disease as so contagious as to render such a sacrifice necessary on the part of the would-be student. Indeed, the whole story is absurd and almost incredible.

Dr. Hamilton Williams, a coroner's physician of this city, has been removed from office on charges of discourtesy and the collection of illegal fees, preferred by Coroner Zucca. Dr. Williams denies the truth of the charges, and disputes the right of the coroner to act as both accuser and judge. He intends to make a fight in the courts for reinstatement.

A New Consumption Cure is announced from Evansville, Ind. The treatment, devised by Dr. Peckinpaugh of Mount Vernon, Ind., consists in the inhalation of smoke from the burning of various kinds of leaves, the fumes of which are believed to possess marked bactericidal properties.

College of Physicians of Philadelphia.—At a stated meeting held October 2, Dr. George McClellan read a paper entitled "An Analysis of the Character of Dr. Physick." A portrait of Dr. Paul B. Goddard, a former Fellow, was presented.

Infectious Diseases in Philadelphia.—The Philadelphia Bureau of Health reports for the month of September 407 cases of typhoid fever, 234 of diphtheria, 214 of pulmonary tuberculosis, 152 of scarlet fever, and 116 of smallpox.

Increased Hospital Accommodation.—The trustees of St. Luke's Hospital in this city have ordered plans to be drawn for a new pavilion for private patients at the northwest corner of the grounds at One Hundred and Thirteenth Street and Morningside Avenue. The pavilion is to cost $300,000. It is reported that Mr. Adrian Iselin, who recently built a home for hospital convalescents on his land near Yonkers Park, is preparing plans for another building. The new structure will be a frame one and will cost about $50,000.

Anti-Vaccination Agitation.—The Board of Education of Philadelphia having decided that, owing to the prevalence of smallpox, all children who, on examination, do not bear marks of having been successfully vaccinated, shall be revaccinated or excluded from school, a body known as the Anti-Compulsory Vaccination Society threatens to take legal steps to restrain the board from carrying out its purpose, contending that the board is exceeding its authority, the Act of Assembly stipulating only that before being admitted to school the children shall produce physicians' certificates of successful vaccination. It is estimated that from 15 to 20 per cent. of the pupils in the schools have not been successfully vaccinated.

The "Nordiskt Medicinskt Arkiv," a Norwegian medical quarterly, has abandoned the use of Norwegian, the original contributions being now published in English, French, or German, chiefly the latter. The contributors will be, as before, Scandinavian medical men (Danish, Swedish, Norwegian, and Finnish), but a staff translator will put their articles in either of the three languages mentioned which they may select, if they have not themselves already written in that tongue. There will hereafter be two parts each quarter, one containing medical, the other surgical, subjects. Dr. Axel Key retains the editorial management.

The Mortality in New York State.—There were 10,999 deaths in this State during August, according to the monthly bulletin of vital statistics issued by the State Board of Health. The number of deaths was 1,300 less than in July, when the rate was excessive. The only material decrease was, however, in deaths from accident and violence, to which heat stroke added 1,300 deaths. In August the heat was the cause of very few deaths. There were five deaths from lightning. Smallpox caused forty deaths, and pneumonia 280. There was an increase in the deaths from typhoid fever, diphtheria, and pertussis.

Obituary Notes.—Dr. JAMES W. DUNPHY died at the home of his parents in this city, on October 1, of pulmonary tuberculosis. He was twenty-six years old, and was graduated from the Medical Department of Columbia University in 1894. He was connected with St. Francis's Hospital for three years, and was also visiting surgeon of St. Joseph's Hospital for Consumptives in the Borough of the Bronx. Four years ago he went to Saranac Lake, in the Adirondacks, and lived there until a month ago, when he came home to die.

Dr. JOHN ELIOT WOODBRIDGE of Cleveland, Ohio, died of cardiac disease at Bad Nauheim on August 31, in the fifty-sixth year of his age. He was a graduate of the Medical Department of the University of Wooster, Cleveland, in the class of 1866. He was well known through his advocacy of the so-called Woodbridge treatment of typhoid fever, a combination of the eliminative and antiseptic methods, through which he claimed excellent results. During the Spanish War he served as surgeon of volunteers, being stationed at Fort Meyer.

Dr. SAMUEL J. JONES, for twenty-five years Professor of Ophthalmology and Otology at the Northwestern University, died in Chicago of stomach trouble, aged sixty-five years. He was a graduate of the Medical Department of the University of Pennsylvania in the class of 1860. After graduation, he served for a time as surgeon in the U. S. Navy. He was a member of the American Academy of Medicine, of the American Medical Association, and of many other medical societies, both special and general. He was attending surgeon in the eye and ear department of St. Luke's Hospital. He was instrumental, a year or two ago, in securing the passage, by the Chicago Council, of an ordinance designed to lessen the city noises.

Dr. E. W. MCCLEVE of Collinsville, Conn., was drowned at Jackman, Me., on October 1. He was graduated in medicine in this city, and afterward spent a year in special study in France and Germany. He was thirty-five years old.

Testimonial Banquet to Dr. N. S. Davis, Sr.—Dr. N. S. Davis, Sr., was tendered a testimonial banquet, October 5, 1901, at the Auditorium Hotel, Chicago. It is estimated that there were three hundred physicians in attendance from the city and various parts of the country.

Dr. Edward F. Wells made a speech in which he presented a loving-cup to Dr. Davis. This beautiful cup, of Grecian design, was, in its lines and proportions, a model of simple, vigorous dignity, and was selected as being peculiarly emblematic of the character and career of the distinguished guest. Engraved upon one side was an excellent likeness of Dr. Davis; upon the other was the leaf of victory, and beneath it the inscription, "*Palmam qui meruit ferat*"—let him who has won it bear the palm; and beneath this, "Pioneer in local and national medical organizations, and in graded medical instruction," and upon the other was this memorial tribute: "Presented to Nathan Smith Davis, A.M., M.D., LL.D., in recognition of his long and distinguished services to medicine, in its every field of usefulness, by the members of that profession which he has so conspicuously adorned, and to whose shield he has given an added luster."

Dr. Davis was received with great enthusiam, and, in accepting the loving-cup, expressed his cordial thanks for the demonstration of kindness.

Progress of Medical Science.

The Boston Medical and Surgical Journal, Oct. 3, 1901.

Infantile Scurvy.—Edward L. Peirson considers this a fairly common disease, which, unlike rachitis, prevails in well-to-do families, where the hygienic surroundings are good. Proprietary foods and absence of fresh milk seem to be predisposing causes at times, but are not always factors in the case. The earliest symptom is swelling of the lower end of the diaphysis of the femur, with tenderness, but with neither heat nor redness. The other symptoms are anæmia and stomatitis ulcerosa. Hemorrhage may occur from the bowels or nose, into the skin, or into any of the internal organs. The child lies with its legs drawn up, dreading to be touched. Treatment consists in giving modified uncooked milk, fresh beef juice, and one-half to one lemon or orange daily. Iron, etc., should be given for the debility and the anæmia.

A Case of Myeloma of the Spine, with Compression of the Cord.—John Jenks Thomas reports the fourth case to be put on record in this country. The patient, a man of thirty years, suffered from general paresis of the legs with other spinal symptoms, with pain in the back, between the shoulders, aggravated by motion and diminished by repose. Operation revealed a tumor in the medulla of the spinous process and lamina of the fourth dorsal vertebra. As much of the growth as could be curetted out was removed. There was complete relief of the paraplegia. The administration of bone marrow and the injection of Coley's toxins resulted in apparently marked improvement in the condition of the bones and of the patient. An interesting feature of the case was the presence of the disassociation of disturbance of the temperature, pain, and touch sensations, such as is seen in syringomyelia, in a case of pressure on the cord from without.

Rachitis.—Arthur R. Crandell gives the symptomatology of this disease in full. The premonitory signs, such as head-sweating, irritability, restlessness at night, prolonged gastroenteric disturbances, and delayed dentition excite suspicion; the detection of the rosary and the enlarged epiphyses render the diagnosis certain. In the treatment, a proper percentage of fats and proteids in the food must be given, and improper elements in the diet eliminated. Large amounts of light and air must be secured, seashore visits or residence must be had if possible, and bathing and massage are useful. Drugs are of minor importance, but cream or cod-liver oil is sometimes needed. Many deformities may be prevented if their possible occurrence is borne in mind. Creeping, walking, and sitting up may cause bending of the softened bones, and should be allowed guardedly until the bones begin to harden. Manipulation may reduce the lesser deformities of the extremities while the bones are feeble. Deformities that are severe require orthopedic treatment.

New York Medical Journal, October 5, 1901

Social Aspects of Dermatology.—In the Fourth Lane Lecture, Malcolm Morris speaks of the bacterial diseases of the skin. The various topics discussed are impetigo contagiosa, boils, carbuncles, anthrax, sycosis, canities, alopecia, and acne, with the addition of paragraphs on affections peculiar to the tropics, such as the diseases caused by the chigoe, Guinea worm, etc. Insistence is laid on the necessity for an improvement in the hygiene of the barber shop and for the more general establishment of laboratories in institutions devoted to the treatment of skin diseases.

Acute Amygdalitis; Its Treatment by the Local Application of the Tincture of Iodine.—This application of iodine is advocated by S. Floersheim, who claims for it the following advantages. 1. The tincture of iodine is the most powerful antiphlogistic in inflammations of the throat. 2. Its action is very rapid, relief being often experienced within five minutes. 3. It has relieved the intense inflammation completely when all other throat remedies had absolutely failed to benefit. 4. Its use in sixty-eight cases of acute amygdalitis has been followed by marked benefit in every case. 5. The method of application is simple.

The Influence of Climate upon Nervous Diseases Considered from a Physiological Standpoint. F. Savary Pearce calls attention to the effect of decreased atmospheric pressure producing a freer circulation in the surface of the body as an important physical and physiological fact in studying the effect of altitude on disease. In neurasthenia, altitudes above 2,000 feet should be avoided, and also high winds. Hysterical subjects also do badly at high altitudes, on account of increased excitability caused by overactivity in the superficial circulation. Both classes of patients are also unfavorably affected in regions where there is a continued prevalence of fogs with low atmospheric pressure. On the other hand, melancholia cases usually do well in high altitudes; for they need increased circulatory activity with correspondingly increased metabolism. Chorea cases do best at a medium altitude, while patients suffering from insomnia are benefited by a sea voyage. Patients with idiopathic epilepsy, if living at an altitude, are apt to improve by coming down to the sea level. Disease of the central nervous system is benefited by a residence in mountainous regions where the air is distinctly dry, while in chronic peripheral neuritis the ideal conditions are found in a region with a dry climate, little or no wind, and at a lesser altitude where the tendency would be to favor the blood current toward the interior of the body.

Medical News, October 5, 1901.

Lager Beer in Acute Vomiting.—Louis Kolipinski advocates the use of lager beer in cases of acute vomiting. The dark beer is preferable to the light. His attention was attracted to this remedy by a patient who evinced a craving for it. The results of its administration were most happy. The after-effects are soporific. It is certain in its action, and intolerance of it is rarely shown. The best results are obtained in women and in those who have not the habit of drinking alcohol. Small doses meet with the best results, *e. g.* a wineglass repeated in half an hour.

Conservative Operations upon the Uterine Adnexa.—Henry T. Byford believes that cases of severe sepsis of the uterine appendages, where there are much pus, elevation of temperature, frequent acute attacks, and complete disorganization of the tubes and ovaries, cannot be treated conservatively, as a rule. But a large majority of the remaining cases admit of the removal of diseased tissue only, without interference with the sexual functions or vigor. The abdominal method gives good results more frequently than the vaginal. Both the immediate and remote results of his conservative operations have been good.

Anæsthesia and Analgesia; a Study of Drug Action and Modern Methods.—William Seagrove Magill defines analgesia as the inability to receive a pain-impression. Anæsthesia would mean a general intoxication of the body, a state of unconsciousness, while the vital reflexes of organic life remain unimpaired; the tissue life and function meanwhile should be affected as slightly as possible outside of the desired period of unconsciousness. The writer then discusses the principal anæsthetics from the chemical standpoint. Safety in the use of any anæsthetic depends far more on the experience and knowledge of the anæsthetizer than on the method or mechanical device used, whatever that may be. The great danger from chloroform is that of primary cardiac syncope. There is little or none of this danger from the use of ether, but the progressive depression of this latter drug is its disadvantage. The final arrest of respiration following this depression occurs undoubtedly more often and is more inevitable than the fatal secondary effects of chloroform. To avoid the initial cerebral excitement caused by chloroform, various expedients have been suggested. The writer advocates the use of ethyl bromide, which must be absolutely pure. In this state it is almost perfectly safe, and after primary anæsthesia has been induced, it may be replaced by chloroform, which may be continued in minute doses, a teaspoonful (in drop doses) being all that is generally necessary for anæsthesia of an hour's duration.

Journal of the American Medical Association, Oct. 5, 1901.

Dangerous Hemorrhage after the Removal of Enlarged Tonsils and Adenoids, with Report of a Case.—A. C. Getchell operated on a delicate-looking girl of five years under ether anæsthesia. Hemorrhage followed two hours later and was repeated at intervals, but under the usual restorative measures, including salt solution under the skin, the child was saved. The history of the case does not make it clear as to the exact source of the bleeding, as no bleeding points could be found in the throat. Getchell advises the postponement of removal of adenoids if a large amount of blood is lost in a preceding tonsillotomy.

A Satisfactory Operation for Certain Cases of Retroversion of the Uterus. The operation is thus described by J. C. Webster: The patient being in the Trendelenburg position, the abdomen is opened, adhesions are separated, and other pathologic conditions which may be present attended to. The fundus of the uterus is elevated and pushed forward. A small hole is then made through the broad ligament on one side under the utero-ovarian ligament near the uterus. Through it a pair of forceps is passed from behind, in order to grasp the round ligament

about an inch from its uterine end. The latter is then pulled through the broad ligament in a double fold. It is carried across the back of the uterus a short distance above the uterosacral ligaments, and is then stitched in this position with chromic catgut. A similar procedure is carried out on the other side, the second round ligament being stitched to the back of the uterus above or below the first and crossing it. The amount or overlapping of the round ligaments depends upon their length and laxity. Each ligament is also stitched to the edge of the hole in the broad ligament. As a result of this operation, the round ligaments are much shortened, and through their new attachment to the posterior and lower part of the uterus act both in elevating the uterus as a whole and in preventing it from returning to its retroverted position. The ovaries are also elevated. No raw surface is produced on which adhesions can form. No new ligament is formed to act as a possible cause of intestinal obstruction, and of trouble in pregnancy and labor. The normal range of uterine movements is not materially altered. There is no possibility of any interference with pregnancy and labor.

Symptomatology of Cerebral Hemorrhage.—F. Savary Pearce thus summarizes the symptoms of this condition, which, in its mildest form, may present only motor aphasia, or cause only an effort when movement is necessary, without any sensory phenomena and without paralysis. But if the hemorrhage has been massive, the patient will, of course, be found comatose. The conjugate deviation of the eyes will occur toward the affected side, the pupils will be dilated, generally one more than the other, and will be only slightly responsive to light stimuli. The reflexes will be found abolished on the affected side at this stage. At the end of a few hours, the knee-jerk and other reflexes, which have been abolished, now return and become increased from day to day, due to irritation of the motor tract from the cerebral lesion, whether it be a hemorrhage, embolus, or thrombus. The patient will breathe heavily; perhaps the Cheyne-Stokes style of respiration will prevail. The temperature will be found increased both on the surface, where the affected side of the body shows an increase of $\frac{2}{5}$ or $\frac{3}{5}$ above the opposite side, the degree of caloric developed being 102 to 103 in the axilla, and slightly above this when taken under the tongue or in the rectum. The patient generally lies supine, the paralyzed extremities may be hyperesthetic, and within an hour or so when consciousness partially returns—if the case progresses favorably—the patient will frequently brush away the clothing or any irritating body, as a house fly, which may light on the paretic member. If the patient is to recover, the temperature drops at the end of four or six hours; the pulse which had been slow and full will become softer, and will increase in frequency to slightly above the normal. Flushing and cyanosis of the face will then disappear, and the mentality be restored gradually, although the mental anxiety and lacrymation may be shown at once in the physiognomy of the patient, aside from any paralysis in the face or lachrymal apparatus. This sudden change of expression of the individual is an interesting and sad indicator of the havoc played by extensive organic rupture in the brain mass. There usually is a secondary rise of temperature even in a favorable case, due, no doubt, to irritation of the heat-regulating mechanism; finally, after six or seven days, the temperature will remain irregular and hovering about the normal line.

American Medicine, October 5, 1901.

The Efficacy of Quarantine and Fumigation in the Prevention of the Spread of Yellow Fever, Without Molesting the Mosquito.—Joseph Waldauer advocates quarantine that will permit commercial intercourse with as little interruption as possible, commensurate with safety. He cites a number of instances, one of which is as follows: In 1897, yellow fever had infected the eastern part of Clinton, Miss. A cordon was placed about the infected center, and not a single case appeared outside of this boundary. The mosquito was there, but seven-eighths of the population escaped the disease. He reports instances in which he believes fomites are alone responsible for the existence of the disease.

The Heredity of Appendicitis.—F. Forchheimer states that in the cases of appendicitis under consideration ethnological causes can be excluded. Gastrointestinal troubles, associated with symptoms on the part of the nervous system and circulatory apparatus, are noted in the earlier generations, appendicitis in the later. The lithæmic diathesis is observed in families where appendicitis has occurred. In certain cases there is a local predisposition to this affection, whose precise character cannot be discovered. The position and direction of the appendix may be affected by heredity, as are its length and lumen. In a general sense, all cases of appendicitis have an hereditary origin.

A Case of Endocarditis Developed During Typhoid Fever.—J. A. Scott reports this case of a man, aged twenty-five years. The diagnosis of typhoid fever was made. Within a few days after admission to the hospital there was considerable dull but constant pain in the epigastric and precordial region. Later, the blood count showed 15,200 leukocytes. Examination of the heart showed visible impulse in the fourth and fifth interspaces, just within the midclavicular line. In the fourth interspace in the nipple line was a breezy or soft systolic whiff, transmitted beyond the nipple and heard in the fifth interspace. On slight exertion there would develop palpitation of the heart, with some rapidity of pulse. As the man grew stronger, the murmur grew louder, and the left heart became more hypertrophied. The second sound was accentuated. Other complications were carefully looked for, but the only abnormality found was in the heart, which was normal on the patient's admission.

Philadelphia Medical Journal, October 5, 1901.

A Lecture on Strangulated Hernia.—Carl Pfister concludes that strangulated hernia is entirely within the scope of those conditions which the general practitioner can treat. Not more than a fair modern surgical education is required. No rarely used instruments are needed. Strangulated hernia is so frequent that every physician should inform himself on the technique of its treatment. Taxis should always be tried unless contraindicated.

The Close Relationship Existing Between Epilepsy and Dyspepsia.—Charles D. Aaron characterizes epilepsy by its periodic loss of consciousness, and general convulsions, which run a typical course. Patients may be perfectly well in the intervals. Epilepsy is caused by functional disturbances in the central nervous system. There is a class of patients whose epilepsy seems directly traceable to gastrointestinal irritation. When one is about to have an attack, the crisis seems to be precipitated by the digestive trouble, and it seems to abate when the digestive trouble is corrected. This trouble is frequently latent. An analysis of the stomach contents and urine should be made in all cases of epilepsy and suspected stomach disorder.

Melancholia and Its Treatment.—George Stockton states that all causes which tend to produce profound mental disturbance are exciting causes of this affection. The disease is more common in females than in males. Ill-health and chronic disease are prominent factors. When a suicidal tendency is manifested, the patient must be most carefully watched. When melancholia relapses into the chronic form, the chances for recovery are very small. Little is known of the pathology of melancholia. In all cases of acute melancholia, there are profound disturbances of the digestive tract. Lavage of the stomach is frequently most valuable. Insomnia is generally present. Hydrobromate of hyoscine is much used, as are also trional and sulphonal. Chloral and conium may be used. Calomel is satisfactory. The bitter tonics are useful. A change of surroundings will sometimes accomplish wonders.

The Lancet, September 28, 1901.

A Case of Acute Double Pneumonia Treated with Oxygen; Recovery.—The patient of G. E. Richmond was a man of twenty-three years, who was of a general robust constitution, and did not appear to have the severe type of toxæmia often seen in this disease. Against recovery were the facts that (1) the pneumonia was double; (2) the disease progressed *pari passu* on both sides until the upper lobes alone were left intact; and (3) the patient fell into a typhoidal state, without delirium, but with respirations of 80 per minute and a pulse varying from 120 to 130, and after the slightest exertion the respiratory rate was anything from 80 to 120 per minute. If this condition had lasted a day or two longer than it did, the patient must have died from lack of respiratory capacity, or if the upper lobes on either side had been attacked, the subsequent dyspnœa must have killed him very shortly. From the time the oxygen was given the temperature began to fall, while before that it had been rising, the highest temperature (104.6°) being reached just before the first inhalation.

A Dilated Superficial Abdominal Vein with a Suggestive History.—T. Fisher presents the history (with illustration) of the case of a mentally deficient girl with a large vein running from the center of the right groin to the costal margin, where it divided into several branches, spreading over the right chest as high as the clavicle. The flow in the vein was downward, not upward. Fisher thinks that in this case there was a blocking of the common iliac vein. At the time that the obstruction of this vein occurred there were convulsions followed by a week's un-

consciousness, terminating in mental defect. There was probably some definite lesion in the brain. This lesion was probably thrombotic. No hemiplegia was noted, and the lesion probably lay outside the motor area. Hemiplegia of acute onset in an apparently healthy child is more difficult to explain. If the paralysis be due to a blood infection resulting in thrombosis of a cerebral vessel, one would suspect some indication of ill-health before the onset of the acute cerebral attack. Generally, however, the child is described as being strong and well at the time of the onset of the convulsions which usher in the hemiplegia. Yet, apparently, other manifestations of a blood infection, such as purpura, may show themselves suddenly, and one would think that the normal condition of the blood must be much impaired before a rigor can take place; but when a rigor is a symptom of commencing acute disease, it has rarely been preceded by any feeling of ill-health which has attracted the patient's attention.

The Prospect of Cure in Cancer.—Horace Manders thinks that the great point in the treatment of cancer is to fix one's attention on the natural forces inherent within the body. We have in electricity, for instance, an agent capable of directly and profoundly affecting the molecular changes that go on within cells, increasing metabolism and resistance to adverse influences. In cancer we may not have to deal with an invading microbe, yet it is evident that some malign source is at work, whose influence the natural defensive powers of the body have become unable to resist, and it is only reasonable to infer from analogy that if these inherent powers could be revitalized to the extent that generally obtains in the equilibrium of health, as has been done in tuberculosis, then there is a definite prospect of a cure for that even more intractable disease—cancer. If these inherent powers did not exist we should all fall victims, as it is unreasonable to suppose that we are not constantly exposed to the source of cancer, just as we are to that of tuberculosis, of which we are now well aware. It is quite possible that the ultra-violet rays of the spectrum have a distinct value in this condition. Yeast treatment is unreliable. The author closes with the statement that in currents of high potential and exceeding frequency we have a means, hitherto unknown, of stimulating the vital energy of cells and of enabling them to utilize, by taking into their protoplasm auxiliary remedies; and that sometimes one and sometimes another, when used in conjunction with these currents, will be found to be the particular one needed.

Diagnosis of Cancer of the Stomach.—J. C. Hemmeter says that the nature and concept of an early diagnosis of cancer of the stomach are intimately associated with a knowledge of the duration of the disease, which can be approximately ascertained by three methods: (1) By observing the rate of growth in cancers that are open to direct inspection, *e. g.* those of the uterus, mammæ, rectum, etc.; (2) by noting the size and rate of growth after the first beginning of subjective and objective complaints in tumors capable of palpation; and (3) by noting the rate of growth in visible or palpable metastases. Cancer of the stomach often occurs in relatively young patients. There is nothing characteristic in the early dyspeptic symptoms. Hæmatemesis occurs in 50 per cent of cases, and constipation in 75 per cent. Hydrochloric acid disappears from the gastric juice, absorption is lessened, lactic acid is generally absent (but this is a later symptom), the peptic and rennet ferments are decreased *pari passu* with the HCl. In the examination of the stomach-contents only two structural elements have a possible diagnostic value, viz., fragments of the neoplasm and the Oppler-Boas bacilli. The urine contains albumin in about 40 per cent of cases, while indican occurs in excess in about 90 per cent. Demonstration of a tumor is the infallible sign, but it often comes very late in the course of the disease. The author would recommend exploratory laparotomy in all cases of gastric disease associated with rapid emaciation, absence of HCl, reduction of proteid digestion under 30 per cent., and the presence of lactic acid, as shown by Uffelman's test, or of numerous long baseball-bat shaped Oppler-Boas bacilli. He thinks little can be hoped for from operation in the case of cancer of the stomach, and looks forward to the possible discovery of a cure through the methods of research now being pursued.

British Medical Journal, September 28, 1901.

The Staining of the Tubercle Bacillus. E. Mello Saunders uses no coverglass at all. As soon as the film has been stained with the carbol-fuchsin and methylene blue and dried, a drop of cedar-wood oil or castor oil can be put on the specimen, which may then be examined with a $\frac{1}{12}$ inch objective. This is a much shorter and less expensive method than the ordinary one.

Foreign Body in the Left Nasal Duct.—A. J. McCloskey was consulted by a woman fifty years old for a left fistula lacrymalis of fifteen years' duration. He saw protruding through the canaliculus what appeared like a shred of tissue. He seized it with a forceps and pulled out a roll of cloth $\frac{3}{4}$ inch in circumference, $1\frac{1}{2}$ inches long, and $\frac{3}{4}$ inch wide. The patient knew nothing of its introduction, but had been to a Bengalese "doctor" a year ago, who had opened a swelling in the position of the present fistula, and he had probably introduced the rag. After the cloth had been removed, the patient made a good recovery.

Case of Strangulated Perineal Hernia.—H. R. Woolbert reports this case. The patient was a large man, aged forty-four years. He first noticed a hard, tender lump the size of a horse bean, at the right of the center of the perineum. Later, the right ischiorectal fossa was swollen and hard. An incision was made to the right of the anus. From the wound there escaped some thin dirty pus with liquid feces, and at the same time there was a protrusion of black, necrotic omentum of very bad odor. A rectal examination showed nothing wrong with the lower gut, but a hard mass was felt in the right side of the pelvis. There was no abdominal pain, swelling, or tenderness. There had been no symptoms to indicate strangulation. Later, the temperature rose to 101° and the pulse ran up to 100 and was feeble. The gangrenous omentum was removed several times. The parts gradually became cleaner. Two deep sinuses remained; one passed up between the rectum and the bulb, and the other upward behind the rectum. The patient refused further surgical aid, and when last heard from had a small sinus behind the rectum.

Berliner klinische Wochenschrift, September 16, 1901.

Babinski's Sign.—H. Schneider has found that, while it is practically true, nevertheless the assumption that the presence of Babinski's phenomenon indicates a lesion of the pyramidal tracts is open to certain theoretical objections. The normal response to stimulation of the sole of the foot consists of two reflexes having different origins. One of these, plantar flexion on slight stimulation, is a cortical reflex, while the other dorsal flexion of the toes, with associated movement of the leg, is evoked by strong stimuli and is of spinal origin. Babinski's sign is present when slight irritation is sufficient to produce dorsal flexion without the occurrence of plantar flexion, and is always due to general increase in reflex excitability. It may be caused in two ways, first, through a break in the pyramidal tracts, whereby the cerebral reflexes are cut off (which is the true Babinski), or, secondly, in conditions of increased spinal activity (*e. g.* strychnine poisoning), or of decreased cerebral excitability (stupor), when the dynamic excess of the spinal response suppresses the cerebral reflex and simulates the true condition.

Soluble Silver as an Internal Antiseptic.—Credé describes the steps which led him, starting from the old-fashioned nitrate-of-silver stick, to evolve his system of silver therapy. The action of silver foil in inhibiting the growth of microorganisms is easily shown by placing it in Petri dishes containing cultures of various bacteria. In this way it is possible to determine the antiseptic value of the different metals, and cadmium is found to occupy the first place, with silver fourth and aluminum last. In this form, however, the use of the metal as a vulnerary is impracticable, and an insoluble salt was sought for. Comparative tests showed that itrol, the citric-acid salt, was the most suitable, and its use during the past five years has justified the author's expectations. He uses it in all operative cases, as well as catgut and silk impregnated with actol (silver lactate). An endeavor to make the valuable properties of the metal available in diffuse and generalized processes brought about the evolution of a soluble preparation, the "argentum colloidale," which is intended for inunction and intravenous use. When it is to be applied by the percutaneous method it is necessary to have a suitable skin, for the lifeless, withered epidermis of the aged does not absorb at all, and even in younger persons some degree of preliminary stimulation by friction with soap and water is needful. The author's observations on the intravenous use of this remedy are still in the preliminary stage, but he describes good results in severe sepsis, pyæmia, acute rheumatism, and advanced pulmonary tuberculosis. The inunctions are valuable in all septic conditions, whether local or general, and an epidemic of unusual severe scarlatina is mentioned in which the method proved of the greatest value.

Münchener medicinische Wochenschrift, September 17, 1901.

The Eczema Question. J. Frédéric contributes an exhaustive study of the bacteriology and histology of this disease and of artificially produced dermatitides, the intricacy of which sufficiently attests the difficulty of the problem involved. No very definite conclusions can be drawn from his results, and the most valuable

clinical deduction is that in every case of eczema the possibility of two sets of causes must be kept in mind, and both internal and external factors in the etiology considered.

An Aid in Seasickness.—R. Heinz calls attention to the close proximity of the vomiting and respiratory centers and describes an experiment on dogs which showed that by inducing apnœa by artificial respiration it is possible, so far, to inhibit the vomiting center as to nullify the effect of emetic subcutaneous doses of apomorphine. Further observations led to the discovery of the fact that by taking several deep breaths in rapid succession a state of sufficient apnœa can be voluntarily produced to counteract vomiting stimuli, and the author recommends that in seasickness, at each crisis, this method be taken to forestall the threatened vomiting.

Acute Sternal Osteomyelitis in Typhoid Fever.—G. Jochmann describes a case of typhoid fever in which, three days before death, pulsation was noted over the sternum on a level with the third rib. Death followed as the result of pyæmic infection, and on autopsy an acute osteomyelitis of the sternum was found. The absence of more marked external manifestations is ascribed to the dense fascial coverings of this bone, which made the inward route the line of least resistance, and in fact it was found that pus had broken through and entered the mediastinum. The pus was found to contain staphylococci, but no typhoid bacilli, a result in harmony with the view that most post-typhoid suppurations are due to the depreciated vitality of the tissues, which makes them an easy prey for pyogenic organisms rather than to specific pus-producing powers of the typhoid bacillus itself.

A Contribution to the Subject of Renal Diabetes.—H. Lüthje describes a case which he considers as affording good evidence of the possibility of a glycosuria of purely renal origin. The patient was a young man who, after an acute gonorrhœa, developed cystitis and nephritis. Soon afterward sugar was detected in the urine, and has been present ever since in spite of periods of rigid dieting which were wholly without effect, while, on the other hand, the consumption of large amounts of carbohydrates did not increase the quantity excreted. We, therefore, have a patient, who, after a renal lesion, developed glycosuria, which probably did not exist before, and which was independent of diet; while, at the same time, the sugar content of the blood was found decreased to a pronounced degree. The author considers that if, as a result of disease, the renal epithelium can become permeable for serum albumin, it may also, in a similar way, lose its power of keeping back sugar.

Deutsche medicinische Wochenschrift, September 19, 1901.

An Interesting Case of Acquired Dextrocardia.—Waibaum's patient was a serving maid of twenty-five, who had for some time been giving symptoms of disturbed cardiac compensation. On examination it was found that the apex beat was in the fourth right interspace, and an *x*-ray photograph confirmed the diagnosis of very marked cardiac displacement. The history revealed no evident attack of pleurisy, and it was assumed that during childhood some such trouble had resulted in the formation of adhesions which had produced the deformity without giving rise to evident symptoms.

Acute Suppurative Perichondritis of the Nasal Septum.—M. Lubinski describes two cases of this unusual affection. One patient was a boy of twelve and the other a middle-aged woman. In the one case, no cause for the trouble could be found, while in the other it was ascribed to the large number of carious teeth in the patient's upper jaw. In both, the symptoms consisted in swelling and tenderness of the entire organ, with the development of an acutely sensitive tumor of the septum. In each instance relief was afforded by ample incision and drainage with curettage, though the septum was left sufficiently damaged to produce marked flattening of the member with sinking in of its dorsum.

The Lymphocytes.—L. Michaelis and A. Wolff believe that the status of the lymphocyte is still far from settled, and that even its recognition is not as easy as is usually supposed. The lymphoid cell is a descendant of the original mesenchyma cell and has definite morphological characteristics, *viz.*, a large round nucleus and a narrow rim of basophile protoplasm. Two varieties of these lymphoid cells may be distinguished: (1) Those still capable of further differentiation, such as the lymphoid marrow cells which probably can undergo transformation into granular cells (myelocytes); and (2) those that have lost all power of differentiation into other types and are the true lymphocytes of Ehrlich. It is only in the normal circulating blood of the adult that these may with certainty be recognized; under these conditions every lymphoid cell is a lymphocyte. In other body fluids, such as transudates, exudates, or pus, the identification of lymphocytes is difficult owing to the presence of degenerated cells, especially polynuclear forms and epithelial cells, which may present nuclei damaged either through (*a*) nuclear thickening (pyknosis) and nuclear fragmentation, (*b*) pyknosis without fragmentation, and (*c*) imbibition. In sections geometrical considerations still further complicate the question; for, while in smears the cells are flattened out and show their nuclear characters plainly, in the tissues a polynuclear cell may easily be cut so as to simulate a lymphocyte.

French Journal.

Concerning the Transformation of Tuberculous Hypoacid Soil into Resistant Hyperacid and Arthritic Soil.—Samuel Bernheim concludes that the treatment of tuberculosis should include the cultivation of a resistant soil. The tuberculous soil is in a condition of hypoacidity and demineralization. The arthritic soil is exactly the opposite. In order to make an arthritic soil in a tuberculous patient, there must be an effort to hyperacidify, to mineralize, and to phosphatize. Hygiene and medication offer us aid. The first will include air, rest, and food, the second, the administration of phosphates and creosote.—*Gazette Médicale de Strasbourg*, September 1, 1901.

A Case of Precocious Menstruation.—Lop reports the case of a girl of six years, born at term of healthy parents. The child had good health till the age of three and one-half years, when she had a rather severe attack of typhoid fever, during the course of which there was a profuse intestinal hemorrhage. At five years she had scarlet fever. When five years and seven months old, she had a decided genital hemorrhage, which lasted eight days. Her health remained good, and since that time she has menstruated regularly each month. Her general condition is good, though the face is a little pale. All the thoracic organs are in good condition. There is no albuminuria, diabetes, or hæmophilia. The genital organs are well formed and of normal size. The mammary glands are small.—*Gazette des Hôpitaux*, September 12, 1901.

Cerebrospinal Meningitis of Syphilitic Origin.—Debove reports this case of meningitis, which occurred in a boy of eighteen years. In May, 1900, he had an attack of syphilis, and the following January was admitted to the hospital suffering from meningitis. The writer believed the disease to be the result of syphilis, for the following reasons: It occurred in the course of a severe attack of syphilis; it coincided with a sharp attack of cutaneous syphilides, ulcerating rapidly; its severity appeared to vary with that of the cutaneous lesions, and it yielded to treatment, antisyphilitic medication being followed by excellent results. Bacteriological examination of the cerebrospinal fluid did not show the presence of any kind of microorganism. There were practically nine punctures made. In the fluid were found lymphocytes and multinuclear leucocytes. The patient was completely cured.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, September 15, 1901.

Employment of Suprarenal Extract by the Oculist.—L. Thilliez has met with the happiest results in his use of suprarenal extract in ocular affections. The solution he uses is composed of equal parts of distilled water and the dried suprarenal powder, which is carefully sterilized and preserved in glass receptacles holding 1 gr. It is a brownish liquid, which is preserved indefinitely as long as the tube is closed. The results are constant. The profound anæmia which is induced in the conjunctiva by its use lasts for one or two hours, according to the individual and the quantity used. Its vasoconstrictor action is especially marked on the conjunctival vessels, but is also seen in the sub-conjunctival or episcleral vessels, and to a slight degree in the deep vessels. The use of this drug is most valuable in intense conjunctival injection. It is useful in cases of keratitis and iritis with injection. Its use has been followed by excellent results in the treatment of glaucoma.—*Journal des Sciences Médicales de Lille*, September 14, 1901.

"Mal de Caderas."—By this name M. Elmassian designates a disease prevalent among horses, characterized by emaciation, fever, and paresis of the hind legs, the last being the most prominent symptom. At a later stage this paresis becomes general, and the animal dies in coma. In sixteen out of eighteen cases the author found in the blood of animals affected with this disease a flagellated organism which he considers to be the morbific agent.

Book Reviews.

PRACTICE OF MEDICINE. By Eminent Medical Specialists and Authorities. Edited by GEORGE ALEXANDER GIBSON, M.D., D.Sc., F.R.C.P.Ed. Physician to the Royal Infirmary, Edinburgh. Vol. I., 824 pp., and Vol. II., 907 pp. Philadelphia: J. B. Lippincott Company, 1901.

THE editor endeavors in these volumes to express the modern English medical teaching and hopes that this is done thoroughly by the numerous coworkers with whom he is associated.

The scheme of the work is much like most of the modern American works which present the subject of the Practice of Medicine in one or two volumes. There are, however, some unusual features worthy of mention. The first hundred pages are devoted entirely to etiological and pathological problems wherein the more general view of disease is succinctly yet ably discussed, and especially those facts which have a practical bearing on the clinical study of pathological conditions; immunity, serum therapeutics, predisposition to infections, etc., all being explained by the most modern theories.

Besides the exhaustive, though usual, article on Nervous Diseases we find incorporated in the text exceptionally thorough articles on the parasites of the intestine, and diseases caused by chemical substances such as lead, arsenic, phosphorus, mercury, alcohol, ptomains, and other poisons.

In the second volume over a hundred pages are devoted to diseases of the skin, and we think wisely, since the general practitioner sees and treats so many cutaneous conditions which are not of necessity seen by a dermatological expert.

In the list of contributors we notice thirty-six, many of whom have written on their special lines for a long time and who also represent many of the different towns and schools of Great Britain.

The work is interesting and authoritative in consequence of this careful selection of contributors, yet we notice some minor omissions and errors such as are apt to creep into all volumes of this character. Under Cerebro-spinal Meningitis there is no mention of Kernig's sign, which, as a clinical phenomenon, has been studied so much of late. We also notice under Yellow Fever the statement that children are rarely affected, whereas the truth is that in epidemics they are especially liable to infection to the extent that it might not improperly be placed among the diseases of childhood. So also in the distribution of typhus fever the fact that it is prevalent in Mexico is ignored. The two volumes are nearly solid text, there being scarcely over a hundred illustrations scattered through the work; had it been profusely illustrated, however, it would have been too bulky, and we scarcely regret the comparative absence, as books are made to-day, of the pictorial art.

We judge the work will meet with the approval of the profession at large as being a good working help, concise, clear, and conservative in teaching, yet fully abreast of the latest investigations—although the omission of the recent yellow-fever experiments seems odd in view of the fact that these volumes are intended for the English-speaking races of all climes.

A TREATISE ON THE ACUTE, INFECTIOUS EXANTHEMATA, including Variola, Rubeola, Scarlatina, Rubella, Varicella, and Vaccinia, with especial Reference to Diagnosis and Treatment. By WILLIAM THOMAS CORLETT, M.D., L.R.C.P. (Lond.), Professor of Dermatology and Syphilology in Western Reserve University; Physician for Diseases of the Skin to Lakeside Hospital; Consulting Dermatologist to Charity Hospital, St. Alexis Hospital, and the City Hospital, Cleveland; Member of the Dermatological Association and the Dermatological Society of Great Britain and Ireland. Philadelphia: F. A. Davis Company, 1901.

UNLESS there is offered to the student a special opportunity of observing the acute exanthemata, accuracy in their diagnosis is often a difficult problem to meet. Perhaps the young physician makes no more mortifying mistakes than in just this class of diseases. The nature of such exanthemata as variola, scarlatina, and rubeola makes it very difficult and sometimes impossible to give the undergraduate sufficient instruction to make him feel at ease when dealing with them. Next in value to experience with the disease itself stands a textbook giving accurate descriptions and showing life-like plates representing the appearance of the skin lesions. Such a volume is the one under discussion. The author states in his preface that it was the need of just such a work when he was young in the practice of medicine that prompted him to prepare the present volume. But it is not only the undergraduate who finds difficulties in the way of acquiring knowledge of these diseases. The opportunities are often just as limited in graduate instruction. The author has had great success in his lantern-slide demonstrations of the acute exanthemata, and this also suggested the value of a volume devoted exclusively to this subject. He embodies in this work the results of modern research. The book contains twelve colored plates, twenty-eight half-tone plates from life, and two engravings. The work of Félix Méheux, *dessinateur et photographe*, of the Hôpital Saint-Louis, Paris, has been secured in this part. There is a most interesting and valuable list of charts and diagrams illustrating various points in connection with these diseases: for example, one showing the influence of wind in disseminating smallpox; another showing the neglect and enforcement of isolation and disinfection of measles; and others showing the course of the fever in various phases of these diseases. There is an introductory chapter giving the early history of the exanthemata which is both interesting and instructive. An addendum gives a table showing the chief features in the differential diagnosis of the acute infectious exanthemata, as well as directions for various methods of disinfection.

THE ESTIVO-AUTUMNAL (REMITTENT) MALARIAL FEVERS. By CHARLES F. CRAIG, M.D., Acting Assistant Surgeon U. S. Army; Pathologist and Bacteriologist to the U. S. Army General Hospital, Presidio of San Francisco, Cal., etc. Illustrated by two colored plates and twenty-one clinical charts. New York: William Wood & Company, 1901.

TOGETHER with the territorial increase that has accrued to this country in the course of the events of the past year or two, we have also acquired a far less desirable heritage of hitherto almost unknown physical ills, and some of our progressive medical schools are exhibiting an enterprise almost commercial in the promptness with which they are instituting chairs of tropical medicine. The appearance of the present volume is therefore very timely, and it cannot but prove of great personal interest to every practitioner in the country, for there is not one who may not at any moment, if he has not already been in that unfortunate position, be confronted with a case that, after baffling all his diagnostic and therapeutic skill, will finally resolve itself into the characteristic picture of this protean infection.

In the space of a brief review it is impossible to give even a résumé of the contents of so important a volume and the original must be consulted for the details of the tertian and quotidian fevers, the two subheadings erected by the author in his consideration of estivo-autumnal malaria. One thing, however, it may not be amiss to underscore by special mention, as it is a point the author reiterates over and over, and that is the absolute necessity of the microscopical investigation of the blood in all suspected cases. The sections on the technique of such examinations and the morphology of the organism are very satisfactory and instructive, but we are surprised to find that although most of the newer stains like Futcher's thionin and the Nocht-Romanowsky are described, no mention is made of Jenner's method, which for simplicity and utility we think can hardly be excelled.

In general arrangement the book is eminently thorough and systematic and it is a matter for great congratulation that the author has seen fit to make public the results of his large experience gained through unusual opportunities for the observation of a still comparatively unfamiliar disease.

A GUIDE TO THE CLINICAL EXAMINATION OF THE BLOOD FOR DIAGNOSTIC PURPOSES. By RICHARD C. CABOT, M.D. With colored plates and engravings. Fourth revised edition. New York: William Wood & Company, 1901.

No other department of clinical diagnosis has developed so rapidly during the past year or two as the subject of hæmology and none of the refinements of laboratory technique have become so popularized as those pertaining to this branch. But in spite of this increased interest and the consequent advances that have been made, progress has really been less rapid than at first sight appears; for in a manner suggesting Penelope's web, each year has demolished a certain amount of the gain that has gone before simply because as statistics increased and observations from different sources were collated deductions made from insufficient material could be corrected, as a single instance the vicissitudes in terminology and percentages which the normal blood count has undergone during the last decade may be adduced.

No better evidence of this shifting ground on which the whole subject stands could be found than is afforded by the radical changes which the rapidly succeeding editions of this book, the most valuable, as it was the first, of its kind in English, have displayed. The present revision has been perhaps the most radical so far, and, in spite of omissions where possible, has increased the

bulk of the volume by nearly sixty pages. The most important changes are those in the sections concerned with pernicious anæmia, leukæmia, typhoid fever, and malaria. Under this latter heading, Ewing's recent studies have been incorporated and the old wood-cuts replaced by very interesting photographs of the organism, which, however, as is too often the case with this class of illustrations, are more pretentious but far less useful than good lithographs would be. Under the heading of hæmoglobin estimation we find descriptions of two new instruments, Tallqvist's and Dare's, which are both to be preferred to the old Fleischl or other forms. The author considers the former of these the best of all for clinical use as combining simplicity, cheapness, and quickness with sufficient accuracy—an opinion with which personal comparisons made in a considerable number of cases lead us heartily to agree.

The wealth of statistical data the book has heretofore offered has been still further increased, and we cannot but feel that Grawitz, who lately said that "he knew of no better book on the subject than Cabot's," did not do more than justice to this most admirable work.

A Handbook of Pathological Anatomy and Histology. With an Introductory Section on Post-Mortem Examinations and the Methods of Preserving and Examining Diseased Tissues. By Francis Delafield, M.D., LL.D., Professor of the Practice of Medicine, College of Physicians and Surgeons, Columbia University, New York, and T. Mitchell Prudden, M.D., LL.D., Professor of Pathology and Director of the Department of Pathology, College of Physicians and Surgeons, Columbia University, New York. Sixth Edition. With thirteen full-page plates and four hundred and fifty-three illustrations in the text in black and colors. New York: William Wood & Company, 1901.

Though the title-page of this well-known work remains unchanged, it is stated in the preface that Dr. Delafield has retired from an active share in the preparation of this edition and that the junior author alone is responsible for such alterations and additions as have been made. The almost universal adoption of this work by the more prominent medical schools throughout the country has already made its general scope widely known, so that although this revision has been so radical as to produce what is practically a new book, for the present purpose it will suffice to mention some of the more important features wherein it differs from the old.

The section on inflammation, replacing that in the old edition, is of such interest and importance that we wish every student attending medical lectures might read it over and over. By an analysis of the methods in which the body responds first to simple and then to more and more complicated forms of injury and of the cellular activities thus called forth, the paramount deduction is made that inflammation is a conservative process and represents the "local attempt at the repair of injury," a concept usually slow to permeate the understanding of the undergraduate. The chapter on infection and immunity is likewise new and presents the data leading to the conclusions of to-day in logical and convincing sequence. The intricate subject of immunization is stripped of most of its hypothetical complications and sets forth in an easily comprehensible manner, the author's closing word that it is, after all, only "the result of an adaptation of normal cell capacities to the special emergency which the introduction of a new environment involves" being a very satisfactory summing up of the little that is definitely known on the subject. In spite of his plea of its being forbidden by the scope of the book, we cannot help wishing that the author had incorporated, at least in a foot-note, some of the theories which the recent work of Buchner, Erlich and Morgenroth, Ascoli, and others has made to seem rather more than plausible. Typhoid fever is treated at greater length and more satisfactorily than before and photographs illustrating the intestinal lesions have been added, together with a short description of the agglutination reaction with some of its fallacies, to which we think a few details as to technique might have advantageously been added. Haffkine's preventive inoculations are also mentioned, but not commented on. Bubonic plague and yellow fever are given more room than in the old volume and a non-committal foot-note refers to the mosquito theory of transmission of the latter. The somewhat antiquated discussion of malaria in the former edition has been replaced by a very comprehensive essay written by F. C. Wood, which embodies the latest studies on this subject and together with its really helpful illustrative plates deserve more than a passing word of praise. The sections on the blood, revised by the same writer, though short, are equally satisfactory and comprehensive. The etiology of tumors receives thoughtful but conservative treatment. The various theories as to the parasitic nature of their causation do not impress the author favorably, and certainly the recent fiasco of Schuller's elaborate pretensions is not calculated to inspire confidence in similar vagaries. The author's view, that rather than to seek a single excitant or group of excitants for these structures it will avail better to devote more time to the study of the obscure influences at work in all tissue growth and especially those controlling morphological and functional specialization, seems eminently more rational.

In Part Three we find noted a new splenic lesion, primary splenomegaly, but the greatest interest attaches to the topics of the lungs and kidneys which have undergone radical changes in their treatment. The formerly involved and blurred classification of tuberculous lesions of the lung has been clarified into a simple and logical system. Dropping altogether the designation phthisis as being inexact and non-distinctive, the subject-matter is arranged under the following heads: 1. Focal or miliary tuberculosis. 2. Tuberculous bronchopneumonia. 3. Complex forms of nodular and diffuse tuberculous lesions. 4. The formation of cavities. 5. Secondary lesions in pulmonary tuberculosis. 6. Concurrent infection. The result of this classification is a grouping as nearly as possible satisfactory from both a clinical and pathological standpoint. The renal lesions have been expurgated in much the same way and we now have a simple yet comprehensive series of pathological types capable of conveying a clear mental picture to the student and still adapted to the use of the scientific pathologist. The section on the nervous system has been relegated to the last portion of the book and contains much new matter, including an admirable plate by F. R. Bailey.

It is unfortunately true that we have long since ceased to demand or even look for literary excellence in medical textbooks, and it would therefore be unfair to close a discussion of this remarkable work without a tribute to the beautifully limpid and well-chosen English in which it is written. Another factor that contributes largely to the reader's pleasure and comfort is the press-work, which is of unexampled beauty and craftmanship, while the illustrations are not equaled in any other treatise on the subject with which we are acquainted. Particularly fine photographic reproductions are those of the heart on pages 391 and 397 and of the intestinal lesions in Chapter VII.

Perfection or an approach to it is apt to be irritating and to stimulate criticism, but we are sure that even envy could find but few flaws in this piece of work, and taking into consideration the importance of the subject it deals with, the source whence its experimental work emanates, the eminence of its authors, and the superlative excellence of the result, there is little doubt that the course of time will show this to have been by far the most important medical publication of the present year.

Dr. Garnault in Berlin.—Dr. Garnault, the French medical man who offered himself to Professor Koch for experiments on the identity of human tuberculosis and perlsucht has arrived at Berlin. He had a long interview with Professor Koch, the language used being English, as Professor Koch does not speak French, neither does Dr. Garnault speak German. Professor Koch declined to give injections to Dr. Garnault, and advised him, if he really wished to do something toward the elucidation of the question, to drink unsterilized milk from a tuberculous cow for about a year, and to abstain as much as possible from other foods. Dr. Garnault agreed to do so, but in addition will have an injection of highly virulent perlsucht bacilli performed every month.—*Berlin Correspondent to Lancet.*

Rat Plague.—Edington (*Centrabl. f. Bakt.*, June 27, 1901), who has been making investigations at Capetown, has isolated from a rat, supposed to have died of plague, a bacillus resembling the plague bacillus in cultures and in its effects on guinea pigs, but differing from it morphologically and in having no effect on rabbits. He concludes as a result of these experiments, that the so-called rat plague is not the same disease as bubonic plague, and suggests that in future in cases where rats die from a disease resembling plague, other animals besides guinea pigs should be used for diagnostic experiment. The disease produced by the organism isolated by the writer resembles in guinea pigs that produced by the true plague bacillus.

Society Reports.

AMERICAN PUBLIC HEALTH ASSOCIATION.

Proceedings of the Twenty-ninth Annual Meeting, Held in Buffalo, N. Y., September 17, 18, 19, and 20, 1901.

THE association met in the Seventy-fourth Regiment Armory under the presidency of Dr. BENJAMIN LEE of Philadelphia, Pa.

There were many representatives present from the United States, Porto Rico, Canada, and Mexico.

Dr. STEPHEN SMITH of New York, one of the ex-presidents of the association, made the Opening Address. He referred to the havoc which death had wrought in the ranks of the association during the past decade, and in giving a history of the public health system of the United States said in part: "Thirty years ago there were not more than three or four well-organized municipal boards of health in this country, but to-day there is scarcely a civil organization without its department of health. Within a single decade this association has been largely instrumental in the development of a complete system of public health administration in this country, namely, municipal, State, and national. A national board of health, which was at one time established by Congress, existed but four years, and for twenty years we have been without such a body, chiefly because of a want of harmony among those who approach Congress on the subject."

Dr. Smith then referred to the early history of the Marine Hospital Service, saying that it was originally created at the close of the eighteenth century in imitation of the English system, when the sailor's home was on the sea, but since the steamship has supplanted the sailing vessel, the sailor's home is at the port. All great advances, he said, in health legislation result from the devastation of epidemic pestilences.

Dr. A. L. GIHON, in moving a vote of thanks to Dr. Smith for his paper, drew attention to the fact that while on his right sat the Director-General of Public Health of Canada, and while on his left sat the supreme head of the sanitary department of Mexico, the United States had no such officer, and said that a demand should be made on the government to make such an appointment.

Out of respect to the memory of President McKinley, and in accordance with the national and State proclamations relating thereto, it was decided to hold no meeting on Thursday, September 19.

Dr. FREDERICK MONTIZAMBERT of Ottawa, Canada, and Dr. EDUARDO LICEAGA of Mexico feelingly referred to the sad event which had just culminated in this city, and extended the sympathy of themselves and their countrymen.

Some Results of the Army Canteen or Post Exchange from the Standpoint of Discipline and Hygiene.—Captain EDWARD L. MUNSON, Assistant Surgeon in the United States Army, read statistics he had compiled from the official records of the War Department, comparing the figures of two periods. The first period, which he called the precanteen period, consisted of the seven years from 1885 to 1891, inclusive. Though the canteen was first introduced in the army in 1889, it was not thoroughly established until 1892. The second period began with that year and ended with 1897. He did not quote figures after 1897, because he did not believe the figures of the last three years of active service in the army could fairly be compared with the figures for a period in the time of peace, although he commented that, as a matter of fact, the figures for 1898, 1899, and 1900 show even a more marked improvement in those conditions of the army that were affected by the canteen than the figures for the six years immediately preceding 1892 showed over the precanteen period from 1885 to 1891. The paper showed that for the ten years from 1878 to 1887 the ratio of soldiers entered upon the sick reports for alcoholism was as 64.28 to 1,000; that this rate was diminished as the canteen was gradually introduced, and that comparing the period 1885–1891 to the period 1892–1897, the statistics showed a reduction of 23.6 per cent. in the entries for alcoholism on the sick list in favor of the latter period. That, whereas, in 1890, before the canteen was fairly established, the number of posts at which the alcoholism entries on the sick list exceeded 10 per cent. of the total strength of the garrison, in the following year the number of such posts was eleven, and each succeeding year the number was reduced until, in 1897, there were only two posts throughout the army which showed a greater rate of alcoholic sick cases than 10 per cent. of their total strength. The author showed that the gravity of the cases of alcoholism also was reduced through the influence of the canteen, and that the number of cases of insanity diminished during the period in which the canteen was thoroughly established.

The profits of the canteen each year were returned to the men for the purpose of buying better food, reading matter, gymnasium and athletic equipment, and in other ways to make their lives more comfortable and the military service more attractive. The writer showed that during the period of 1892–1897 there was an increase of 13.3 per cent. in the number of soldiers making deposits with the army paymaster over the number for the precanteen period, 1886–1891. Also that the average number of convictions by court-martials for drunkenness during the precanteen period was three hundred and seventy-two a year, whereas the average number after the canteen was established was but one hundred and sixty.

Much might be said to show the remarkable influence which the canteen, with its restricted sale of beer and light wines, has had in preserving the health of troops, maintaining discipline, and promoting temperance; but in view of the figures given further argument on the subject would seem to be unnecessary. The canteen, as formerly operated, was a positive element for good, and is so regarded by 95 per cent. of the more than six hundred officers of the army who have made reports to the Secretary of War concerning its influence.

At the conclusion of Dr. Munson's paper, the following resolution was offered by Dr. Charles A. Lindsley of New Haven, Conn., which was adopted:

"*Resolved*, That this body deplores any action in curtailing the operation of the army canteens or post exchanges, and in the interest of general and military sanitation and temperance recommends their establishment as formerly existing in the United States."

Dr. CHARLES R. GREENLEAF, an army surgeon, described the sanitary conditions in the Philippine Islands since the United States came into occupancy of them.

Tuberculosis.—Dr. FELIX FORMENTO of New Orleans, La., read a paper with this title, in which he stated that in medicine a certain spirit of conservatism was required. There seemed to be nowadays too much laboratory work, and not enough bedside practical instruction. While he did not deny the glorious discoveries in bacteriology, he feared that the study of man in health or disease was often sacrificed to that of the infinitesimal microbe. The discovery of the tubercle bacillus was one of the greatest events of modern medicine, unifying into one classification many affections considered as being of a different character; also making diagnosis perfectly certain; it was shown that the disease was communicable from man to man—that the sputum of consumptives was the great carrier of infection; but was it not going too far to affirm that tuberculosis was only transmissible by contagion and that heredity played no part in this transmission? The observation of sanitarians had shown that heredity, as in cancer and other affections, was a powerful agent of transmission. Some cases of direct transmission to the fœtus in utero had been observed. Without hereditary predisposition, local infection would remain sterile

in the great majority of cases. The air swarmed with microbes, and those who were predisposed succumbed. In order that a seed might develop two conditions were required—an active seed and a proper soil. The same is true of a disease germ. All debilitating causes by lowering the powers of resistance furnished a favorable nidus for the development of the tubercle bacillus. War should be waged on the bacillus, and we should try to exterminate it by all possible means, as well as to destroy the sputum; the disinfection of rooms occupied by consumptives was important, and a rigid inspection of milk and meat necessary in spite of the claims of Professor Koch. International measures should be adopted among nations for the disinfection of railroad trains, steamers, hotels, etc. Marriage of consumptives should be prevented. All places where numbers congregate should receive special attention, and the general public, when once informed, would become a most powerful auxiliary in the crusade against tuberculosis.

Dr. JESUS CHICO of Mexico read a paper in which he detailed some observations tending to prove that the meat and internal organs of tuberculous animals brought about the appearance of tuberculosis in the persons who ate them.

The British Congress on Tuberculosis.—Dr. FREDERICK MONTIZAMBERT, Director-General of Public Health of Canada, read a paper on this subject, in which he laid great stress on the curability of the disease, if taken in time, and all agreed in regarding human sputum as the chief medium of infection. He stated that the feature of the Congress was the address by Dr. Koch, more particularly that part dealing with the alleged non-identity of bovine and human tuberculosis, and the non-transmissibility of the disease. His (Koch) actual words in this connection were: "Though the important question whether man is susceptible to bovine tuberculosis is not yet absolutely decided, and will not admit of absolute decision to-day or to-morrow, one is nevertheless at liberty to say that if such a susceptibility really exists, the infection of human beings is but a very rare occurrence. I should estimate the extent of the infection by the milk and flesh of tuberculous cattle, and the butter made of their milk, as hardly greater than that of hereditary transmission, and I therefore do not deem it advisable to take any measures against it.

"On the other hand, current view and practice of local sanitary authorities in England have been in accord with the findings of two royal commissions that 'any person who takes tuberculous matter into the body as food incurs risk of acquiring tuberculous disease.'"

Dr. Montizambert stated that the feeling throughout the Congress seemed to be that the statements of Koch were made prematurely and upon insufficient data. The position of eminent authorities who criticised Dr. Koch's announcement was essentially uniform.

After the reading of Dr. Montizambert's paper, there was a general discussion on the subject of tuberculosis, which was participated in by several members of the association.

Dr. Chico of Mexico read the paper of Dr. FRANCISCO BERBALDEZ on "Remarks Intended to Show the Character of Human Vaccine as a Preventive of Smallpox."

At the Tuesday evening meeting, Mr. ANSLEY WILCOX of Buffalo delivered an address of welcome. He paid a glowing tribute of affection and respect to President McKinley, and among other things said: "When we think of the way in which the American people calmed themselves in their intense grief, and the reins of power dropping from lifeless hands were taken up peacefully by the strong hands of the appointed successor, we will say again with heartfelt joy, whatever may happen to our individual leaders, 'the Government at Washington still lives,' and towers among the nations of the earth as our electric tower amidst the beautiful buildings surrounding it."

President's Address.—This was delivered by Dr. BENJAMIN LEE of Philadelphia, who referred to the overwhelming grief with which the representatives of one of the nations composing the association were now stricken. He said that among the problems with which the association had to deal was that of the protection, safety, and welfare of the community against the possible infection of leprosy; that the moral leper was sometimes infinitely more dangerous than the physical leper. The anarchist was the moral leper, and it was high time that we undertook to limit the spread of this, the most horrid of all infections.

He complimented the city of Buffalo upon its condition of health and cleanliness, and expressed the wish that the association might leave with the city some lessons which would be helpful in the administration of health matters.

The next meeting was held on Wednesday, September 18, at which time reports were read of the Committees on Pollution of Public Water Supplies, Etiology of Yellow Fever, and cases of yellow fever observed on the two coasts of the Mexican Republic, from September 17, 1900, to August 31, 1901.

One of the features of the meeting was a paper by Dr. WALTER REED of Washington, D. C., on yellow fever, which was in part as follows: "We were able, under strict rules of isolation, to bring about an attack of yellow fever in ten non-immune individuals out of a total of thirteen by means of the bites of mosquitos—the Stagomyia fasciata—that had previously been fed with the blood of yellow-fever patients during the first, second, and third days of their attacks. We were thus able to establish in the most practical manner that the mosquitos serve as the intermediate host for the parasite of yellow fever. At the same experimental station we were able to demonstrate that yellow fever cannot be induced through contact with the clothing and bedding of yellow-fever patients, even though these articles had been previously thoroughly soiled with the excreta of such patients."

Dr. Reed then described in detail the mosquito which carried the infection of yellow fever, as to its history, method of propagation, habitats, breeding places, method of generation, and measures that should be taken to prevent them from infecting healthy individuals, and guarding the sick against bites of these insects. He said the life of this mosquito was about five days, if deprived of water, and if a voyage at sea had consumed more than that time, the mosquitos contained in the hold of the vessel would have perished unless they had access to water or moisture, and the danger of infection lay not in the cargo or personal baggage, but in the individual sick with the disease. In 1901, there was a reduction of 83 per cent. in yellow fever in the city of Havana.

A paper was presented by Dr. A. H. Doty, Health Officer of the Port of New York, dealing with the practical methods of quarantine necessary in view of the changes in our belief in regard to the necessity of disinfection in yellow fever.

A recess was then taken until 3 P.M., at which time resolutions were adopted to the effect that every effort should be made by sanitarians to diminish the mortality of tuberculosis; that sufficient facts have not been offered by Professor Koch to prove that human and bovine tuberculosis are different diseases; that municipalities should make regulations against expectoration; that they should compel notification by physicians of cases of tuberculosis; that they should establish municipal sanatoria for the benefit of persons in families of limited means; that tenements, factories, workshops, schools, and other public institutions should be inspected in order to promote cleanliness, ventilation, and other sanitary conditions.

A paper was read by Dr. GORGAS covering about the same ground as the one submitted by Dr. Reed.

A general discussion of the subject of yellow fever was then indulged in by the members of the association, and

some of the members, among them Dr. Formento and Dr. Wasdin, dissented from the views expressed in the paper of Dr. Reed. They maintained that yellow fever was probably transmissible by fomites. However, Dr. Reed, in his closing remarks on the subject, was very sanguine of the position he had taken, and claimed that the experiments conducted in Havana were absolutely conclusive.

Several reports were submitted during the afternoon, among which was the report of the Committee on "The Relation of Forestry to the Public Health," by Professor William H. Brewer of New Haven, Conn.; also, a report on "Bacterial Purification of Water by Freezing," by Mr. H. W. Clark of Boston, Mass. Professor S. H. Woodbridge of Boston submitted the report of the Committee on "Car Sanitation."

At the session on Wednesday evening, Dr. A. WALTER SUITER of Herkimer, N. Y., read the report of the Committee on "The Cause, Prevention, and Duration of Infectious Diseases."

This was followed by the report of the Committee on "Disinfectants and Disinfection," by Dr. Hibbert W. Hill of Boston, Mass., after which there was a short discussion on them.

On Thursday, the third day of the meeting, there was no business transacted, but the President called the meeting to order at 10 o'clock as usual, at which time resolutions of sympathy and regret in regard to the death of the late President McKinley were passed unanimously by a rising vote.

Drs. William Bailey of Louisville and C. P. Wilkinson of New Orleans made short speeches on the resolutions, which were very appropriate and much appreciated, after which the association adjourned until Friday morning at 10 o'clock.

The association met Friday morning at 10 A.M. Considerable time was taken up in reading various reports, the election of officers, and the appointment of committees.

Notes on the Necessity of Attending to the Hygiene of the Mouths of Pupils of Schools.—This paper was read by Dr. JUAN BRENA of Zacatecas, Mexico. The author stated that the bacillus of Koch had a predilection for the buccal cavity of the mouth, which greatly favored its multiplication. He said it had been demonstrated that whatever the form of oral sepsis might be, it was susceptible of causing all the phlegmoses connected with the local organism. Many cases of septic diseases of the mouth were due to dental caries, and to that alone.

The Influence of School Life Over Health.—A paper on this subject was presented by Dr. Frank W. Wright of New Haven, Conn. The author said, in part, that the first principles of school hygiene were embodied in the sites for the building, construction, and furniture. With proper care, natural ventilation was superior to artificial ventilation. Some of the diseases affecting children were near-sightedness, diseases of the spine, disorders of the digestive system, tonsillitis, consumption, and contagious diseases. Nervous diseases were not at all infrequent, and affected the teachers as well as the pupils. Impure air, defective light, and mental strain were the principal causes of these troubles. Many failures were due to the long hours. The exercise and refreshment taken during intermission were not of the right nature, and the lunches were sometimes made up of sweets and other indigestible food. The first great care, on the reassembling of school, was to see that all pupils were successfully vaccinated. Previous to the discovery of vaccination, smallpox killed more people than all other scourges combined. No child from a house in which a contagious disease existed should be allowed to attend school, and any person exposed to a contagious disease should not attend school for at least two weeks after the last exposure. While whooping-cough was not particularly fatal to older and more robust children, it might be contracted at school and communicated to other members of the family. He thought it was of the greatest importance that pupils should have nothing in common, as it was well known that children with contagious diseases often attended school for several days before it was discovered that such was the case. Such diseases might be communicated by pencils, drinking-cups, books, and clothing. An examination of the pupils should be made daily for the prevention of contagious diseases. An examination should be made twice a year of the eyes and ears of each pupil, and outside inspection was important when children were absent from school.

Hygiene in Its Relation to the Primary School.—Dr. GUZMAN of Mexico followed with a paper on this subject, and among other things he said that aid to the physician must come from the teacher. In his belief, teachers should be trained to help the inspecting physician so as to be able to discover diseases produced by ill-directed schoolwork, contagious diseases in the school, examination of the physical condition of pupils at the time of their entrance to school, and at regular intervals thereafter.

Cremation in Its Relation to Sanitary Legislation.—Dr LUIS G. ESPINOZA of Vera Cruz, Mexico, read a paper with this title. He divided the subject into three parts: (1) The merits and demerits of cremation; (2) the establishment of hygienic regulations in cemeteries, and a discussion of their respective value; (3) he concluded in favor of compulsory cremation in contagious diseases.

There were several reports of committees and a few papers which were not read, owing to lack of time, as there were no sessions held on Thursday; but these papers and reports will appear in the official proceedings of the association.

The following officers were elected for the ensuing year: *President*, Dr. Henry D. Holton, Brattleboro, Vt.; *First Vice-President*, Dr. Walter Reed, U. S. Army; *Second Vice-President*, Dr. Jesus Chico, Guanajuato, Mexico; *Secretary*, Dr. Charles O. Probst, Columbus, Ohio; *Treasurer*, Dr. Frank W. Wright, New Haven, Conn.

New Orleans, La., was selected as the place for holding the next annual meeting, but the exact date was not determined.

NEW YORK COUNTY MEDICAL SOCIETY.

Stated Meeting September 23, 1901.

NOMINATIONS.—*President*, Dr. Frank Van Fleet; *First Vice-President*, Dr. C. N. Dowd; *Second Vice-President*, Dr. Robert Lewis, Jr.; *Treasurer*, Dr. E. W. Peet; *Secretary*, Dr. J. Van Doren Young; *Assistant Secretary*, Dr. E. P. Fowler. The nominations also included one hundred and seventy-five delegates to the State Society.

Report of the Milk Commission.—Dr. HENRY DWIGHT CHAPIN, the Chairman, read the report. He said that since last November over eight hundred bacteriological tests had been made, under the supervision of the commission; also, that thirty visits to farms had been made by the members, and ten conferences had been held with the milk dealers of this city. The bacteriological examinations were made by Dr. Sarah Belcher and were made possible by a grant from the Rockefeller Institute for Scientific Research. Circulars embodying the suggestions as to the care of milk that have been made by the United States Department of Agriculture were sent broadcast throughout the milk-producing areas of the State. In looking for a cause of the deteriorated milk found in this city, it was finally determined that this was due to microbic agencies. From a chemical standpoint the milk was always good. The law requires a 3-per-cent. butter fat, whereas the average found exceeded 4 per cent. The entire history of the milk, from the cow to consumer, was studied step by step.

It was deemed advisable that a fixed standard of clean milk should be established, and to those dealers who

reached that standard a certificate should be issued. Their milk is called "certified milk." This standard is that the acidity must not exceed $\frac{2}{10}$ of 1 per cent., must not contain more than 30,000 bacteria to the c.c., and must yield 3½ per cent. butter fat. Out of twenty samples of milk examined on a winter day, the range extended from 13,000 to 128,000 bacteria in each c.c. On a summer day, with the thermometer at 62°, it varied from 500,000 to 220,000,000 per c.c. The large number of bacteria is due almost entirely to dirt that gets into the milk. The number of bacteria found in the milk depends on seven conditions: (1) Cleanliness of the barn; (2) condition of the cow; (3) of the milker; (4) of the utensils; (5) the cooling process; (6) the transportation; (7) the cleansing of the bottles before they are returned by the consumer. It was found that if a cow was milked in an ordinary barn in its usual unhygienic condition, the milk yielded 120,000 bacteria to the c.c., whereas the same cow, when milked by the same hand in an open pasture, gave a milk with 20,000 bacteria to the c.c. When the tail, udder, and groin were not cleansed, other conditions being proper, a count of 90,000 bacteria to the c.c. was obtained; after cleansing these parts, it was reduced to 2,000.

The milker should be clean-shaven, and should wear clean linen clothing. Young single men were preferable, because married men were more apt to carry infection from their children.

If the milkpail was not cleansed specially, a count of 80,000 to the c.c. was obtained. After sterilization, this was reduced to 5,000. All of these counts were made twenty or thirty times, and always gave the same results. Metal strainers are not advisable, because the dirt is broken up and disseminated. Absorbent cotton or gauze held fast to the can by clean clothes-pins is the best strainer. Aeration as practised by the ordinary farmer is not a success. The increased number of instruments increases the likelihood of infection. The object of æration is to get rid of the "cow odor" of the milk. This odor is not present if the milk is clean and has a low bacterial count.

A low bacterial count at milking will always be low if the milk is cooled to 45° F. within twenty minutes, and kept at that temperature. No matter how low the count may be, if we wait longer it will be high. The average temperature of springs, which are the usual places to cool the milk, was found to be 55° F. This is 10° too high, and for this reason ice is always a necessity for the milk farmer. The cans should be surrounded by ice and kept at 40° until they are taken out of the car. The car should be kept closed, and the temperature kept as low as possible. The consumer should be instructed to cleanse and scald the bottles before returning the same.

In families where a contagious disease exists, the bottles should be demolished. The farmers and milk dealers have entered into the work of the commission most enthusiastically. All of the dealers that have come up to the standard have kept their milk below the standard of 30,000 bacteria to each c.c. throughout the past summer, whereas in former years the average milk found in this city yielded from 500,000 to 220,000,000 bacteria. Several forms of stoppers for the bottles have been recommended by the commission.

Dr. W. H. PARK said that the Health Department had recently passed a resolution (1) that no milk would be received in New York City next year the temperature of which registered more than 50° F., and (2) that all milk unnecessarily contaminated will not be received. The milk ordinarily received that had been exposed to the sun's heat often furnished one billion bacteria to the c.c. The method of counting bacteria consists in diluting each c.c. 100 times, and counting the number of colonies, and in this way estimating the total. The kind of the bacteria was not determined. A low count, if no antiseptics are used, always means cleanliness. A high count does not always mean bad milk, but it does mean either dirt or insufficient cooling. In connection with the [illegible] Institute, experiments have been in progress in various parts of the city during the past summer to ascertain the effect of various forms of milk on infants among those fed on breast milk. There were a few cases of diarrhœa but no deaths.

In the second class, milk from clean farms, low in bacteria and then boiled, was used. In the third, milk from clean farms, but high in bacteria and then boiled, was employed. There was no difference in the results from the use of the second and third classes. There were but few fatalities in these classes. In the fourth class ordinary cheap grocery milk was employed. The parents were told to go to their own groceries and get the milk which was paid for by the institute. All of these children had diarrhœa and nearly one-fourth died. Pasteurized milk when two days old generally caused vomiting and diarrhœa.

Dr. HENRY KOPLIK said that the acidity of the milk is a good index of the number of bacteria in it. If the acidity be very high, no matter how high or low the bacterial count may be, the milk is unfit for use.

Mr. TUTTLE expressed his appreciation of the work from the dealer's standpoint. He advised that the Board of Health should clean up the rural cow-barns.

Mr. HORTON said that about one million pints of milk are sold daily in this city. A great deal of the contamination occurs after the milk is delivered, the poorer classes not using sufficient ice to preserve the milk.

Dr. WENDELL C. PHILLIPS asked if there is any extensive employment of preservatives by the milkmen in this city and if it is harmful to do so.

Dr. W. H. PARK said that during the hot weather 12 per cent. of the milk delivered in the city contained more or less formaldehyde. Lately it has fallen to 1 per cent. After observing children fed on this preserved milk he is not able to say that it does any harm.

The report was further discussed by Mrs. Van Zandt, Mr. Bennet, and Dr. E. D. Fisher. A vote of thanks was given to the milk dealers and the committee was instructed to continue its labors.

A Fibrocyst of the Cæcum.—Dr. THOS. H. MANLEY presented this growth. All of the classical symptoms of appendicitis were present, and the blood examination pointed to pus. No pus was found. Leucocytosis, he said, is an unreliable sign of the presence of pus in the abdomen.

MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Fifty-first Annual Meeting, Held in Philadelphia, September 24, 25, 26, 1901.

First Day—Tuesday, September 24.

DR. THOMAS D. DAVIS of Pittsburg, President, called the meeting to order at 10 A.M. Prayer was offered by Rev. Dr. H. C. McCOOK of Philadelphia.

The address of welcome was made by Dr. GEORGE ERETY SHOEMAKER, President of the Philadelphia County Medical Society.

Hon. SAMUEL H. ASHBRIDGE, Mayor of Philadelphia, extended a welcome on behalf of the city.

Dr. JOHN H. MUSSER, Chairman of the Committee on Arrangements and Credentials, presented the program and made announcement of various clinics. Invitations were also extended to visit and inspect the hospitals of the city.

The Secretary, Dr. C. L. STEVENS, reported a total membership of 3,460, which was a net increase of 111 members.

The Board of Trustees reported that the financial affairs of the society had been prosperous. A recommendation was made for a change in the by-laws by which the Committee on Nominations shall be directed to fix a date between the 15th of September and the 15th

of October of each year for the holding of the meeting of the society. The death of Dr. John Curwen was reported. Dr. Curwen had long been a most respected and useful member of the society, once the President, and at the time of his death he was a member of the Board of Trustees.

The Committee on Pharmacy recommended that the Legislature be asked to pass an act requiring all persons seeking hospital or dispensary aid to record their names and addresses, and when unable to write them, make their marks, as in legal documents. If it is found that persons able to pay are fraudulently receiving aid, it is recommended that a penalty be inflicted.

Dr. HENRY BEATES, Chairman of the State Board of Medical Examiners, called the attention of the society to the fact that, though great advances had been made under the law governing the practice of medicine, the conditions were yet far from the ideal.

Some Aural Complications of Influenza.—Dr. S. MACCUEN SMITH of Philadelphia in this paper stated that influenza has been recognized and treated as such for ages, the epidemics having always been characterized by intervening periods during which the disease seemed to have been banished. Brief mention was made of mastoid complications and the importance of their early recognition, and the adoption of energetic measures for relief of local symptoms and the prevention of additional complication of even more serious import was insisted upon.

Dr. CHARLES H. BURNETT of Philadelphia said that when the so-called epidemics of grippe or influenza broke out in 1889 he had been practising otology seventeen years, and he had never seen any case of so-called grippe presenting symptoms which he had not seen previous to the spread of this affection. The hemorrhagic form he did not think any more prevalent in grippe than in measles. He believed there was no specific excitant in influenza.

Address in Otology.—Dr. E. U. BUCKMAN of Wilkesbarre delivered this address. Changes that had taken place in the progress of otology in recent years were noted. Mastoiditis, which had been looked upon with considerable dread, was now, with the present methods of radical operation, so successfully treated that abortive measures were employed but for a short time. Tinnitus aurium he regarded as one of the least satisfactory conditions to deal with, and one in which there had been little progress in the last five, possibly twenty, years. Electrolysis in obstinate tinnitus and increasing deafness had been beneficial. Success, however, was more dependent upon the way medicines and instruments were used rather than upon what remedies or appliances were used.

Dr JOHN B. ROBERTS offered a resolution that the Committee on Publication, in conjunction with the Board of Trustees, consider the propriety of publishing a directory of the physicians of Pennsylvania.

Incudectomy in the Treatment of Progressive Hardness of Hearing, Tinnitus Aurium, and Ear Vertigo.—Dr. CHARLES H. BURNETT of Philadelphia maintained that in this disease the surgeon had to contend with a trophoneurosis of the muscular structures of the middle ear, and not simply with a chronic catarrhal process. The latter condition often accompanied symptoms of progressive hardness of hearing and tympanic vertigo, but when the catarrhal symptoms were relieved the aural symptoms often remained unchanged. The proneness of progressive hardness of hearing to pass from one ear to the other was noted. The mode of treatment best adapted to arrest the progress of disease in the one ear and to prevent its occurrence in the other, advised by Dr. Burnett, was to remove the incus from the worse ear. The operation must be performed upon the etherized patient, and with the aid of the electric lamp (six volts). Observation of the patients for periods of ten to thirteen years had proven the efficiency of the operation.

A Few Reasons for Early Operation in Acute Mastoiditis.—Dr. WILLIAM H. DOBLEY of East m read this paper. He stated that there is a variety of acute mastoiditis usually a sequel to chronic purulent otitis media, which at no time presents any serious local symptoms. In some of these cases the swelling may be moderate in amount, the tinnitus not great, and at no time is there severe pain or other general disturbance; yet, when given sufficient time, the disease may become so extensive as to threaten the patient's life. Cases illustrative of this condition were cited. Aside from the intractable chronic otitis media purulenta which may follow these cases, if the condition is allowed to continue, there may ensue extradural abscess, meningitis, cerebral abscess, or septic thrombosis of the lateral sinus, each with its attendant fatalities. He believed that the dangers attending mastoiditis not operated upon in the early stages have not been sufficiently impressed upon the mind of the profession.

Dr. B. ALEXANDER RANDALL of Philadelphia believed that many of the mastoid inflammations were not purulent and did not need operative intervention; at least four out of five cases of redness, swelling, and tenderness of the mastoid, in his experience, did not require operation, but would clear up under proper medication and rest.

Some of the Ocular Affections of Childhood Associated with Impaired General Nutrition.—Dr. S. D. RISLEY of Philadelphia presented this paper. He did not attempt to discuss the more frequently occurring forms of strumous eye disease in very young children, but gave briefly the clinical history of two cases illustrative of a form of ocular disease frequently occurring during adolescence, but not necessarily dependent upon the peculiar conditions of vitality at that age. He gave a graphic picture of the general conditions which were described as malaise, variability of temper, precarious appetite, intermittent albuminuria, high specific gravity of the urine, excessive urates, and frequent deposition of red crystals. In both cases boggy turbinates and pharyngeal adenoids developed, and the eyes passed while under observation from hypermetropic to myopic astigmatism. This change of refraction through distention of the eyeballs was preceded and accompanied by retinochoroidal disease, impaired sharpness of vision, photophobia, injected conjunctiva, fronto-occipital headache, and general nervous symptoms; in one case by chorea minor. In discussing the conditions presented by this group of patients, Dr. Risley raised the inquiry whether, given the general impaired metabolism and the absence of the congenital astigmatism, the ocular conditions would have occurred. He believed that they would not, but said that, given the abnormal refraction condition, the observed ocular disease and stretching of the balls were much more likely to occur in the presence of the abnormal state of the general nutrition.

Dr. MCALLISTER of Reading asked for diagnostic points which would determine operation.

Dr. BURNETT of Philadelphia stated his belief that operation was indicated in the presence of one or more of the three symptoms—pain, pyrexia, and prolapse in the posterior upper portion of the auditory canal. He referred to the paper of Dr. Shepherd of Brooklyn on "Acute Mastoiditis Following Acute Otitis Media," which he considered one of the best he had ever read.

Gumma of the Ciliary Body.—Dr. EDWARD STIEREN of Pittsburg, in a paper with this title, said that syphilitic invasion of the deeper parts of the eye, especially the acquired form, usually calls for a guarded prognosis. A detailed report of an apparently hopeless case was given. The patient was first seen in November, 1899, and the diagnosis of tertiary syphilis made. Treatment was continued only until March, 1900; although treatment for two or three years had been advised. In December, 1900, the patient reappeared for treatment, which was continued uninterruptedly until May 1, 1901. The patient was next seen on July 10, when there was perfect move-

ment of the eyeball. A slight accommodative squint was corrected by the occurrence of a cycloplegia. The round pupil was slightly displaced upward and inward. The only evidence of the gumma was a slaty discoloration of the sclera and the displaced pupil. The anterior capsule of the lens was dotted with a score of fine deposits near the periphery.

Contagious Diseases of the Eye and Their Treatment.—Dr. S. Lewis Ziegler of Philadelphia briefly outlined some practical methods of treatment, which if applied early and efficiently would, he said, bring about speedy convalescence and avert dangerous complications and sequelæ. The contagious diseases were classified under catarrhal ophthalmia and purulent ophthalmia. He spoke briefly of acute catarrhal conjunctivitis and granular conjunctivitis. Prophylaxis in these conditions was an important element. The local treatment was given. The purulent inflammations were described with their symptoms. In the treatment of ophthalmia neonatorum the successful prophylactic measures were limited to three applications of Credé's ointment, irrigation of the eye with mercuric bichloride solution 1 to 4,000, and irrigation with a solution of protargol of from 10 to 25 per cent.

Paresis from a Standpoint of the General Practitioner.—Dr. Robert H. Chase, Superintendent of the Friends' Asylum for the Insane, at Frankford, Philadelphia, took this as the subject of the annual "Address on Mental Disorders." The importance of the subject was brought to the attention of the general practitioner and his responsibility pointed out. The disease in its initial stage should be intelligently studied by him for the especial reason that this favorable season is the only time during the course when any treatment is likely to succeed. The history of the disease was given, showing that to the pupils of Esquirol belongs the distinction of its discovery. The prominent theories given in the past respecting its nature were stated briefly as follows: (1) As a complication of insanity; (2) as a distinct form of insanity; (3) if not as a group of cerebral or cerebrospinal affections, at least as a paralytic dementia, with which is associated more or less frequently, and under various conditions, insanity. The interesting history of the prodromal stage was briefly sketched. The early signs of the disease, as seen in general practice, were described at length, and the treatment in this stage, including prophylaxis, was outlined.

Two Cases of Progressive Muscular Dystrophy in Brother and Sister.—Dr. A. A. Eshner of Philadelphia reported these cases occurring in a boy of thirteen and a woman of thirty-two years. The cases were considered interesting apart from the relative rarity of the muscular dystrophies, because of their occurrence in two members of the same family, of the history of another dystrophy in the collateral ancestry, and of the presence of a traumatic cerebral disorder in the father. Muscular dystrophies were stated to be hereditary or familial diseases, sometimes congenital. Their appearance, as a rule, occurs during the first decade of life. They are more common in males than in females in the proportion of about six to one. They rarely, if ever, occur in negroes. The essential lesion of the disease, so far as known, consists in degenerative changes in the muscle-fibers, some of which are increased, while others are diminished in size, together with more or less hyperplasia of the interstitial connective and fatty tissue. The etiology, the author stated, was obscure. The view was expressed that the most plausible explanation of the lesions was that which attributes them to some developmental defect, resulting in the replacement of muscular by fatty and fibrous tissue, with secondary motor disability and the consequent deformities. The disorder is usually progressive in course, and the prognosis is consequently unfavorable. Massage and electricity were mentioned as aids in preserving tissue and preventing deformities. Surgical correction of the deformities might be required.

Prognosis in Neuritis.—Dr. F. Savary Pearce of Philadelphia believed that in summing up scientific clinical facts of carefully studied cases of neuritis there would be found existing signs and symptoms indicating the ultimate results in different classes of cases dependent upon pathological findings, variety of cases, etc. Examples of needle prick and gunshot wounds, as unfavorably affecting nerve tissue, were given. The prognosis in such traumatic cases was said to be very grave. Pressure neuritis should be differentiated from the palsies of occupation neuritis. Degeneration of peripheral nerve trunks after severance was regarded as of grave prognosis unless the operation of suturing was done either primarily or secondarily. The diathetic causes of neuritis, as of rheumatism, gout, etc., are usually local and responded in proportion to the general disease. Neuritis from alcohol and the metals is usually recovered from in the first attack if the poisoning had not been too profound. Tumors, such as false neuromas, when the cause of neuritis, should be excised by the surgeon.

Some Cases of Hysteria.—Dr. Edward E. Mayer of Pittsburg, in a paper with this title, emphasized the statement that hysteria is always a psychic disease, and that the various motor, sensory, secretory, and vasomotor symptoms are but the result of this primary mental condition. The altered psychic condition is based upon altered relations between actual consciousness and subconsciousness. Stigmata of degeneracy are generally found in hysterical persons. The treatment advised by the author was a psychic one, mental or suggestive therapeutics being necessary. A number of interesting cases was described, among which was one with double ptosis (spastic), rhythmical contractions of the diaphragm and upper arms, paraplegia, etc., which had lasted for four years and was cured in three weeks. Another case was one of blue hysterical œdema of the left hand. A third case was one with successive attacks of hystero-epilepsy, mutism, somnambulism, multiple neurotic (hysterical) gangrene, and paraplegia.

Second Day—Wednesday, September 25.

The President's Address.—Dr. Thomas D. Davis of Pittsburg delivered the annual address, taking for its title "Pioneer Physicians of Western Pennsylvania." He described the perils and privations experienced by the doctors who crossed the Alleghanies in the latter part of the eighteenth century. In ministering to the sick and wounded, many of these brave men suffered death at the hands of the Indians. "The pioneer doctor," said Dr. Davis, "was often a farmer, a minister, or a school teacher. He traveled over several counties, and often made long and perilous journeys."

The Address in Medicine was delivered by Dr. John B. Donaldson of Canonsburg. He said the present century's achievements promised far to outstrip the past. Internal scientific medicine with preventive means will be the work of the medical world. Surgery, the brilliant half sister of Medicine, would go hand in hand with her in the crusade against disease, and the profession might certainly look for other Jenners to arise who will eliminate many of the fatal but preventable diseases of our day. The hope was expressed that, in the great Keystone State of Pennsylvania, the present century might see legislative bodies willing to legislate in the interests of indigent tuberculous patients. The relief for these patients was an important field, to his mind, toward which the minds of philanthropic millionaires might be directed. Ere long he believed that there would be an end to the so-called different schools of medicine, for all would be compelled to practise rational medicine.

Movable Kidneys; Their Effect upon the Gastric and Intestinal Functions.—Dr. Boardman Reed of Phila-

delphia read this paper. Nephroptosis, he said, was frequently one feature of a general sagging downward of a number of abdominal organs. Glenard's division of movable kidney into three stages was given: That in which only a part of the kidney can be felt below the ribs; that in which the entire kidney is in the flank between the last rib and the ilium; and that in which the kidney may be felt anywhere in the abdominal cavity between the last rib and the pelvis. The female sex is more prone to the condition. Movable kidney in the author's opinion was conducive to the causation of chronic appendicitis. Symptoms mentioned include pain or sensitiveness on pressure over the site of the displaced organ, and certain dyspeptic symptoms. The writer advised complete rest in bed in the severer cases with much pain, and later the support of a well-fitting pad and belt, with special exercise and very cautious massage to the abdominal muscles; outdoor air, tonic hydriatic treatment. When such treatment fails, or is not practicable, surgical treatment must be employed.

Dr. R. H. GIBBON of Scranton regarded the application of a pad to a loose kidney a mistake. This had been pointed out by Edebohls, who laid great stress upon the fact of appendicitis having been frequently caused by a loose kidney displaced downward, causing interference with the superior mesenteric vein, resulting in congestion and inflammation. He believed that surgical treatment was the proper method in the majority of cases. The only external device of value in his opinion was the Cardigan corset, with the lacing reversed, *i. e.* beginning at the bottom.

Dr. CHARLES P. NOBLE said his personal experience had been limited to surgical treatment. When the mobility did not exceed two or three inches, he believed the rest cure, with general tonic treatment, was useful. If the urinary symptoms are negative, the case required little attention. Marked symptoms showing congestion of the kidney indicated nephrorrhaphy.

Dr. Reed, in closing the discussion, said movable kidney should not be considered *per se* necessarily a surgical disease. In the cases where the circumstances would not permit the rest cure, he thought operation should be done.

Enteroptosis.—Dr. JOHN G. CLARK of Philadelphia spoke upon this subject. He dealt more especially with the mechanical part of the treatment. He felt that in the majority of cases the more conservative plan should be first tried. He had seen cases in which there was a general sagging of the pelvic floor with retrofixation, and in which not infrequently after operation the patient complained of the dragging sensation. He referred to the article by Webster of Chicago, which he regarded of signal interest. Models were shown illustrative of the abdominal wall muscles looking from the front and from the back, and the pathology demonstrated.

Dr. GIBBON of Scranton thought the fibrous sheaths of the muscles were at fault rather than the muscle tissue itself.

Report of Several Cases of Infective or Malignant Endocarditis.—Dr. A. O. J. KELLY of Philadelphia said that during recent years our ideas concerning the nature of acute endocarditis had undergone considerable modification. Formerly, it was customary to distinguish two forms of acute inflammation of the endocardium—one, a benign, non-infective process, ending in the recovery of the patient, these usually with permanent damage to the valves affected; the other, a malignant, destructive infective process, running a comparatively short course and ending in the death of the patient. It had long been observed that clinically the differential diagnosis between the two forms is sometimes attended with considerable difficulty. It had been ascertained that all cases of acute endocarditis are associated with, if not due to, bacteria; that the same bacteria are found in cases associated with ulceration as in those that are not, and the necessity for revision and modification of our conception of acute endocarditis became apparent to all. Three factors of diagnostic value were: (1) Leukocytosis; (2) bacteriologic examination of the blood; (3) irregular heart murmurs.

Dr. A. E. ROUSSEL referred to three cases of endocarditis occurring in his practice, two of which possessed features resembling those of Dr. Kelly's second case. In a girl of nineteen, the diagnosis of malignant endocarditis of the ulcerative type was confirmed by death. In many of the cases he thought it might be well to leave off the term "ulcerative" altogether; in many of the cases, the tissue changes have gone as far as death without the presence of ulceration. The term "malignant" would seem to cover the ground. On the other hand, this term might be objected to because some of the cases got well. These were a small minority, however. A point of great interest in the second case was the progressive enlargement of the spleen. Leukocytosis was also marked. The third case was of interest in that it followed miscarriage and presented all the symptoms of a profound septicæmia. The blood was taken from the vein, and Dr. Roussel emphasized the importance of taking a large amount of blood for examination bacteriologically.

Dr. J. M. ANDERS spoke of the difficulty in diagnosis in the two forms of endocarditis, and emphasized the great importance of studying the cases minutely by the application of the most modern methods. He thought some value should be placed upon the presence of murmurs even in so-called ulcerative endocarditis. Of more importance were the embolic phenomena. His constant rule was carefully to eliminate all affections simulating ulcerative endocarditis, particularly typhoid fever and the allied diseases.

Dr. JAMES TYSON thought that if the process were looked upon as a pyæmic one, in which the heart valves become the objective point of the bacterial effect, the question would be greatly simplified.

A Few Notes on the Salts of Sulphocarbolic Acid.—Dr. EDGAR MOORE GREEN in this paper mentioned a few of the sulphocarbolates which he had found excellent in intestinal antiseptics, notably the sodium, potassium, and ammonium salts administered in pill form with enteric coating. Sodium sulphocarbolate with acetanilid he advocated for the relief of headache, especially associated with deranged digestion.

Primary Abdominal Tuberculosis.—Dr. LAWRENCE F. FLICK of Philadelphia in this paper defined the condition in question as the primary existence of a tuberculous colony in some tissue or organ within the abdominal walls. The general belief that tuberculosis began in the lungs was, he said, based upon the common experience that the first recognition of the disease is in the lungs; not until these organs are affected do the classical symptoms occur. The observations of pathologists and surgeons have proven that tuberculosis does frequently occur primarily within the abdomen; in what percentage is yet undetermined. Diagnosis is often impossible, and in this direction surgeons and gynecologists could aid much. Frequent discussions of the subject were urged. The question of treatment is still unsettled; men of the largest experience recommend early surgical intervention. As an alternative to this the building-up treatment is advocated by others.

Dr. JOSEPH PRICE, in discussing Dr. Flick's paper, said that if the surgeon could see these cases, the treatment would be very simple and, as they often had occasion to think, very fortunate. For a number of years he had never refused to open the abdomen for intraperitoneal tuberculosis, whether ovarian, tubal, general, or of whatever nature. He considers iodoform abundantly used of great value. The condition of abdominal tuberculosis he considered one which justifies excessive and undue liberty intraperitoneally, and which could be undertaken in no

other condition. Iodoform should be used freely and drainage employed, either pelvic or general.

Dr. MORDECAI PRICE expressed his belief that the infection occurred through the lymphatics and the blood through some disorganization of the digestive tract with food infected with tuberculosis. He had seen several cases apparently directly traced to the milk product. In diagnosticating intraperitoneal trouble, where there was slow emaciation, he believed it was the urgent duty of the surgeon to open the patient and investigate.

Dr. JAMES TYSON stated that in the difficult diagnosis the tuberculin test presented an infallible test.

Dr. S. SOLIS COHEN said that the use of iodoform in a clinical experience extending over a great many years had convinced him of its value in combating tuberculosis, internal or external. In the internal administration the secret of its efficacy is in the gradually increasing dosage, taking some three or four months to reach a maximum. The question of etiology was important. With the conflicting theories as to the transmission of human and bovine tuberculosis the etiology was unsettled. That bovine tuberculosis can be transmitted to cattle, or bovine tuberculosis transmitted to man, he thought there was sufficient evidence upon record from careful observations in the clinic and laboratory to make the profession very careful at this time not to give the impression that such transmission is not possible.

Dr. Flick, in closing, stated that the tubercle bacillus could enter the alimentary canal through other sources than food and milk; the bacilli entering the respiratory tract might lodge in the pharynx and be swallowed; these bacilli might be from a consumptive as easily as from food and milk. In the same way the germs could be carried into the bronchial glands, the thoracic duct, and into the circulation. He laid special stress upon the value of iodoform and the preparations belonging to the same group.

Election of Officers.—The following is a list of the officers elected: *President*, Dr. F. P. Ball of Lock Haven; *First Vice-President*, Dr. Walter Lathrop of Hazleton; *Second Vice-President*, Dr. A. S. Harshberger of Lewistown; *Third Vice-President*, Dr. R. W. Stewart of Pittsburg; *Fourth Vice-President*, Dr. H. K. Weaver of Norristown; *Secretary*, Dr. C. L. Stevens of Athens; *Assistant Secretary*, Dr. W. B. Erdman of Macungie; *Treasurer*, Dr. G. B. Dunmire of Philadelphia.

Dr. G. W. Guthrie, Dr. W. Murray Weidman, Dr. W. S. Foster, and Dr. A. P. Hull were elected delegates to the House of Delegates of the American Medical Association, to serve for two years. Dr. W. T. Bishop, Dr. John B. Roberts, and Dr. H. S. McConnell were elected delegates to serve for one year. Sixteen alternates were elected, and it was recommended by the committee that Dr. William M. Welch of Philadelphia should be selected to serve as the fourth delegate for one year, should the society be entitled to eight delegates.

The place of the next meeting will be Allentown.

Afternoon Session—Wednesday, September 25.

Address on Hygiene.—The afternoon session was opened by the address on Hygiene by Dr. E. B. BORLAND of Pittsburg. Special hospitals for the care of smallpox, diphtheria, and scarlatina patients in populous centers were declared to be a necessity. The advertisements of patent medicines and medical frauds were deplored. It was stated in regard to the water supply of the Commonwealth that about 20 per cent. only used water that was normal. The rest of the community were obliged to use water admissible, suspicious, or dangerous. Preventive medicine was declared to be as exact a science as clinical medicine.

The Histories of Three Accidents in Tapping the Chest.—This paper was read by Dr. J. C. LANGE of Pittsburg. The cases were: One of instant death following the entrance of an aspirating needle through the seventh intercostal space at the posterior axillary line on the left side; male, aged twenty-three years, failing to regain health after attack of croupous pneumonia. Cure was effected by tapping, condition now normal, except slight lack of fulness in subscapular region, and difference of one and one-half inches in expansion of the two sides. The third case was that of a woman aged fifty-eight, with biliary cirrhosis attacked with acute pleuritis of the left side. Restoration to condition of health was compatible with the liver lesion. Death occurred, however, sixteen months later without any complications of liver disease.

Reforms in Medical Education.—Dr. H. M. SHALLENBERGER of Rochester in this paper deplored the low standard of equipment of the average medical graduate in comparison with graduates in other sciences or in the polytechnic schools. A preliminary examination of students, admitting only those who have had an adequate education, and a change of the curriculum, giving a uniform standard in all colleges, embracing a comprehensive course of study and including all collateral branches with special stress on clinical and bedside instruction, were the two remedies suggested.

In discussion, Dr. E. B. BORLAND remarked upon the necessity of raising the standard of medical requirements. In regard to examinations, he was "in favor of examining all the way round, beginning with the student asking admission to a medical school," which examination might well extend to members of faculties and of State medical boards of examiners.

Dr. J. C. BATESON of Scranton believed that higher medical education should be general and include all sects practising the healing art.

Dr. HENRY BEATES, Jr., emphasized the high responsibility of the Medical Society of the State of Pennsylvania in elevating the standard of medical education. Commercialism was rife, and the result was the admission of men as students utterly incapable of comprehending the science of medicine.

The Duration of Immunity from Diphtheria Antitoxin.—Dr. HENRY D. JUMP of Philadelphia presented this paper. With a patient who had been exposed, it was his practice to inject as much as 500 units of antitoxin. After the isolation of the sick person, the room was disinfected, and all persons not affected were given an immunizing dose, being removed. A series of cases was given.

Lay Medical Education.—Dr. E. N. RITTER of Williamsport in this paper stated her belief that school teachers were capable of instructing pupils of the lower and intermediate grades, but that physicians should instruct the advanced pupils. Higher classes should be instructed in "First aid to the injured, with practical demonstrations." The preservation of health should be taught. The importance of the selection of a healthy life partner was emphasized.

Strength.—Dr. JOHN M. BATTEN of Downingtown stated that a perfectly healthy parent governed the sex of his or her offspring; if the father were strong, the offspring would be a female; if the strength of the mother should prevail, the offspring would be a boy.

The Vermiform Appendix.—Dr. EDMUND W. HOLMES of Philadelphia read a paper by this title, and presented a fine collection of specimens. The four varieties of cæca according to Treves were given. In the examination of one hundred and ten adult appendices, he had found the first variety but once, the second but once, the third ninety-six times, the fourth twelve times. The tendency was shown of the cæcum to encircle the ileocæcal valve as a pivot, and so carry the appendix toward the left. A search for the base should on this account be made to the left, the ileocæcal valve itself being a valuable land-

mark when the usual band is indistinct. He believed that the displacement of the appendix or the displacement of the cæcum and colon *en masse* might explain anomalous symptoms. Palpation of the appendix through the abdominal wall was not always reliable, owing to the displacement of the organs.

Dr. JOHN B. ROBERTS congratulated Dr. Holmes upon the valuable contribution in the presentation of the paper and specimens.

The Doctor's Fee; Is It Fixed and Definite?—Dr. L. J. LAUTENBACH of Philadelphia read a paper by this title. The amount of the physician's fee was determined, in his opinion, by the doctor's reputation, skill, the time consumed, risk incurred, and responsibility assumed. The patient's standing, obedience, and the result of the treatment are also influencing factors. The practice of fraternal societies of supplying medical services for a nominal sum was deplored. He believed that in every case doctors should charge a fair price, which, if not paid, should be collected.

Therapeutic Notes.—Dr. LINNÆUS FUSSEL of Media called attention to a few remedies which appeared to him of great value, some well known, but none fully recognized as the acceptable treatment among the majority of the profession. Among those mentioned were tincture of iron in acute rheumatism in doses of 30 minims every six hours; ipecacuanha in dysentery, giving first $\frac{1}{4}$ grain of morphine, applying a mustard plaster to the epigastrium, and in half an hour a dose of 20-30 grains; hydrargyrum in rhus poisoning; cider vinegar in diarrhœa; calomel as a specific in most forms of skin disease. Many other conditions were enumerated with the remedy and dosage.

Some Respiratory Conditions Dependent upon Gout and Obesity.—Dr. J. M. ANDERS of Philadelphia stated that the conditions present in the lungs in obesity should be more thoroughly observed. He attributed the symptom of dyspnœa so frequently present in the anæmic variety of obesity largely to mechanical interference with the respiratory function, though hæmatologic and muscular changes entered into the causation. Special attention was called to the thoracic symptom of pain in the subscapular and intrascapular muscles. This pain might be acute, and might be localized, though it commonly extended across the back. Dr. Anders described also hyperæmic bronchitis with troublesome cough and copious mucoid expectoration occurring in over-fatness. Intimately associated with this bronchitis was asthma, due largely to transient insufficiency of the heart muscles, and an asthma due to gastric disturbance. His tentative conclusions concerning the relation of asthma to polysarcia were: that asthma occurs in about 5 per cent. of the cases of obesity; that it occurs only in extreme polysarcia; that there is a gouty state or history in most cases in which true asthma is secondary to obesity; that about 50 per cent., or one-half, of the cases are curable by overcoming the causative condition.

A Medical Examination as a Prerequisite to Marriage.—Dr. J. C. BETTS of Scranton remarked in this paper that, instead of regarding the many thousands of unhappy marriages yearly as the natural result of violated physical law, many people piously criticise the severity of Providence. The question of hereditary influence, for a number of years agitated by the writer, was receiving attention in the proposed scientific regulation of marriage in some States. He believed that all applicants for marriage should pass a medical examination. For the preservation of the integrity of the race and the physical welfare of the republic, legislators should be prompted by the medical profession to give the subject active attention.

The Diagnosis of Lesions of the Aortic Orifices, with Special Reference to Functional Aortic Insufficiency; Pseudo-Leukæmia, with Enlargement of the Liver and Spleen, Due to Lymphatic Tuberculosis; A Case of Typhoid Fever Complicated by Noma, with the Demonstration of Diphtheria Bacilli in the Necrotic Area.—Dr. JOSEPH SAILER of Philadelphia presented these papers. He did not attempt to read them all, giving a mere outline of the second case. He referred in this connection to the investigations of General George M. Sternberg, who had found fifteen cases in all in which the lymph glands showed peculiar histological enlargement and in which tubercle bacilli could be found by staining. These investigations were the most important that had been made, in that they constituted the first systematic effort to prove that pseudo-leukæmia of a certain peculiar type was not a blood disease, but an infectious one, and that the infection was produced by tubercle bacillus. The total number of reported cases is only about thirty. In the short space of six months three such cases had come under Dr. Sailer's observation, in four of which it was possible to confirm the diagnosis before death, in two by the autopsy. The general features of the cases were given. The temperature chart showed a singular irregularity occurring nowhere else except in chronic pyæmia, differentiation consisting in the absence of leukocytosis. Attention was called to this peculiar group of cases because so few had been recorded. Dr. Sailer thought with those who had written upon the subject that the cases escape recognition because the pathological changes are not invariably those indicating the existence of tuberculosis, and the clinician is probably satisfied with the diagnosis of leukæmia or Hodgkin's disease.

Thursday, September 26—Morning Session.

The President, Dr. THOMAS D. DAVIS of Pittsburg, called the meeting to order at 9.30.

A resolution recommending personal visitation to disinterested county medical societies was offered by Dr. MCCONNELL of New Brighton, and referred to the proper committee.

Psycho-Physical Laboratory.—A resolution was introduced expressing the favor of the society in regard to the establishment of a psycho-physical laboratory in the Department of the Interior at Washington for the practical application of physiological psychology to sociological and abnormal or pathological data, especially as found in the institutions for the criminal pauper and defective classes, and in hospitals, and also as may be observed in schools and other institutions. The resolution was accepted as read.

Dr. GEORGE ERETY SHOEMAKER offered a resolution recommending compulsory vaccination in schools.

Governor STONE gave a few words of greeting to the society. To the physician he accredited the strongest hold on the pulse of the country.

President McKinley's Physicians.—Dr. JOHN V. SHOEMAKER offered a resolution to the effect that the physicians and surgeons in attendance upon our late President, William McKinley, convey the fullest confidence of the members of the Medical Society of the State of Pennsylvania, who record their appreciation of the labors of the doctors in attendance, knowing that they faithfully performed their duties, though grieving that their efforts were in vain to save their distinguished patient.

Address on Surgery.—The scientific meeting was opened by the address in surgery entitled "Torsion of Arteries," by Dr. JAMES W. MACFARLANE of Pittsburg. The author divided torsi into "free" "limited" and "fixed." Free torsion was said to be the rule. He believed that when this form failed, primarily in a large artery, the ligature, compression, and perhaps the entire hæmostatic forces of the surgeon were required. Advantages mentioned were saving of time, absence of danger from foreign bodies, and the requirement of no assistant. A table of cases in which torsion was employed was given with results.

The Operative Treatment of Female Bladder; Descent and Sacculation.—Dr. GEORGE ERETY SHOEMAKER of

Philadelphia in this paper stated that displacements of the bladder in the female might take place upward, backward, laterally, forward, and downward. Only in the downward direction is sacculation and imperfect evacuation liable to occur frequently, but its secondary effects are very important. The writer has seen but one case of pathological forward dislocation. The various displacements with their symptoms are described. Operations above the pubis have little effect upon the bladder's position, if unsupported by other measures. The plan adopted by the writer is given in detail. Special attention is called to the method of taking up the redundant anterior vaginal wall and supporting the bladder.

The Present Status of the Bottini Operation as a Method of Treatment in Obstructive Hypertrophy of the Prostate Gland Derived from a Summary of 834 Operations by Forty-eight Operators.—Dr. ORVILLE HORWITZ, in this paper, declared his belief that prostatic hypertrophy generally commences much earlier than at fifty years of age. He quotes Dr. L. Bolton Bangs, who agrees with him in this view. He regarded the experience of trustworthy surgeons a guarantee of the value of the operation. The operation of complete prostatectomy he thought was attended with far greater danger than the Bottini, and should only be attempted in rare instances. The complication of contraction of the vesical outlet had not occurred in Dr. Horwitz's cases. Pyelitis is not necessarily a contraindication. A series of conclusions is appended.

Surgery in Its Relation to Neurasthenia.—Dr. G. D. NUTT of Williamsport presented a paper by this title dealing with the correction by surgical means of certain prominent symptoms of a neurotic nature caused by disease of the sexual organs, movable kidney, errors of refraction, and muscular insufficiency of the recti muscles of the eye. Since pathological conditions cause nervous symptoms not directly connected with the affected organs, the question was raised, Might there not be other diseased organs causing reflex disturbance yet unknown, to account for the large and increasing number of neurasthenics?

A paper entitled "Tuberculosis of the Rectum," by Dr. W. M. Beach of Pittsburg, and one entitled "Some Practical Points in the Treatment of Typhoid Fever," by Dr. S. Birdsall of Susquehanna, were read by title.

Rare Complications of Appendicitis, with Their Treatment.—Dr. ERNEST LAPLACE presented this paper. The cases exhibiting these complications had had history of a previous acute attack cured by medical measures, but lingering obscure abdominal pain. Such cases had been diagnosed as affections of nearly every organ in the abdomen. The necessity of proper surgical intervention was emphasized in consideration of the difficulty in diagnosis. Particularly, Dr. Laplace stated, was this necessity apparent when it was realized that pain may be absent in acute appendicitis, or felt at an entirely different spot, or that fever may be absent or range to 104° or 105°, and that a general disturbance and local rigidity are perhaps the only constantly present symptoms of the disease. It should be borne in mind in every case of appendicitis that there was a time when operation would have saved life.

Dr. JOSEPH PRICE, in discussing Dr. Laplace's paper, made the statement that "more people are dying to-day of appendicitis than from an epidemic of smallpox." Chronic cases, he said, ought never to occur. Well-marked symptoms late in the cases evidenced the fact that the early symptoms should have been detected by a good clinician. He believed the public would come to hold the clinicians thrice responsible for early diagnoses. The complications mentioned in Dr. Laplace's paper should have been prevented by proper recognition of the early conditions.

Dr. ADOLPH KOENIG of Pittsburg said that he was a general practitioner, and as such believed that the general practitioner should use good judgment. He had been in practice twenty-two years and had never yet lost a case of appendicitis which he had had from the beginning. If he saw that a case was not improving under medication, he would call in a surgeon, but asserted that a surgeon had no right to operate in a mild inflammatory condition mistaken for appendicitis.

Dr. MORDECAI PRICE remarked the sentiments of the paper and the expressions of Dr. Joseph Price. His common experience of meeting physicians who had never seen a case of appendicitis, he thought, was explained by the fact that the condition was not recognized. In any intraperitoneal inflammation he thought you could safely operate for appendicitis ninety-eight times out of a hundred.

Dr. Laplace, in closing, said that inasmuch as the complications are numberless and the diagnosis often difficult, the patient should be given the benefit of the doubt and the chance of recovery by immediate operation. If the appendix could be purged of its offensive material by drastic measures, this should be done. Should the pain reappear after having disappeared, nothing could do justice but the cold steel blade. If everybody were justly dealt by, we would not hear of a case of appendicitis. An "unsuccessful operation" meant that somebody had blundered; the medical man had treated too long, "or the surgeon has been a dirty surgeon." With the present understanding of appendicitis the patient should live.

The Radical Cure of Hernia was the title of a paper presented by Dr. EDMUND W. HOLMES of Philadelphia.

A Case of Perforating Typhoid Ulcer; Laparotomy; Recovery.—Dr. W. L. RODMAN of Philadelphia read a paper by this title. The case presented typhoid ulcer in the fifth week, followed by extensive general peritonitis, and was operated upon thirty-seven hours after the accident. The perforation was found directly under the incision. The opening was rapidly closed with Lembert sutures, and the cavity flushed with hot saline solution. A large amount of iodoform gauze was introduced as protection from further infection and to favor drainage. A drainage tube was introduced at the lower end of the wound. Although the patient was in extremis, with a pulse that could not be counted, he is to-day perfectly well. The time of operation from beginning to end was sixteen minutes. Dr. Rodman's impressions were that a case of perforation, even though in general peritonitis, should have the benefit of a laparotomy if in a hospital with proper facilities; and that general anæsthesia can be borne even in so grave a condition. Ether was given. Cocaine was considered, but the patient was too young to give intelligent co-operation. Operation was at least thirty-seven hours after perforation. This case, with one of general peritonitis following gunshot wound of the intestine and operated upon successfully fifty-one hours after the accident, has taught Dr. Rodman that it is rarely ever too late to give such cases the benefit of surgery. The proportion in which pathological perforations of the gut in typhoid fever repair themselves without surgical intervention has been estimated at between 3 and 10 per cent. The rule of action in civil practice should be just the opposite to that in military practice, where it may be proper to decline interference because of lack of facilities. The analogy between traumatic and pathological perforations of the intestines involves the same general principles, and as early a laparotomy as is consistent with the existing shock should be done in both. Dr. Rodman believes it is as much man's duty to operate in both conditions as it is to tie a bleeding vessel in hemorrhage.

Dr. JOSEPH PRICE considered the operation in this case the acme of good surgery.

Dr. ELLA B. EVERITT, physician in charge at the Woman's Hospital, said that it had been with the greatest interest that she had watched the case. Drainage from the tube was continued for a week after the operation,

and drainage from gauze a day or two later. Pus cells were present, but no active organisms were found. She thought the lesson was evident that such patients were entitled to operative interference, even though, as this child, almost moribund. The severity of the attack was so great that it seemed that the child hardly could have lived even without this grave operation. The result was doubly gratifying. The occurrence of a small hemorrhage after the operation was also noted as a second complication. The child rallied well from this, and went on to a satisfactory recovery.

Dr. Elizabeth Bundy said the point of interest to her was the range of the persistent temperature. The condition of the child had begun to improve within an hour from the time of the accident

Case of Ascites, Due to Syphilitic Cirrhosis of the Liver.—Dr. W. J. Roe of Philadelphia presented the report of this case seventeen months after the beginning of ascites, and fourteen months after the first paracentesis he transplanted the omentum between the parietal peritoneum and the abdominal wall, suturing the omental border of the stomach and colon to the margins of the artificial pocket. Previous to operation, paracentesis was performed thirty-one times, with an average of 760 ounces and of fourteen days' interval; subsequent to operation, twenty-one times, average ounces 218 and twelve days' interval. Marked improvement in her general health ensued. After six months, her general condition reverted to that at time of operation, and death occurred at the end of eight months. Autopsy showed extensive vascular adhesions, a horseshoe kidney, and syphilitic cirrhosis of the liver.

Ludwig's Angina Complicating Typhoid Fever.—This paper by Dr. William E. Robertson and Dr. Charles A Biedert of Philadelphia was read by title.

Afternoon Session—Thursday, September 26.

Address in Obstetrics.—The annual address in obstetrics was given by Dr. David Funk of Harrisburg. Dr. Funk presented the status of several of the more serious obstetrical complications and operative procedures. From the standpoint of the general practitioner, it was stated that placenta prævia would probably remain one of the most disquieting and alarming complications for the reason that there can be no prophylaxis and because of the appalling rapidity with which it destroys life. Symphysiotomy as an operation of election would appear to be gradually displaced by cæsarian section, where the high-forceps operation is dangerous. Puerperal septicæmia and ectopic gestation were considered fully. The responsibilty of the general practitioner in making an early diagnosis in ectopic gestation was emphasized. Previous history of sterility, cessation of previously regular menstrual history, irregular bleeding, colicky pains, nausea, and vomiting were given as points in differential diagnosis. Puerperal eclampsia in its etiology and treatment was considered; as to etiology, writers are agreed upon the single point of toxæmia Serum therapy in the treatment is regarded as a problem of the future.

The Ultimate Results of Operation for Cancer of the Uterus. Dr. Charles P. Noble of Philadelphia stated the greatest problem before the medical world to-day to be the causation and cure of cancer. Recent literature shows that hysterectomy for cancer of the cervix cures about 10 per cent. of cases, based upon the standpoint of freedom from recurrence at the end of five years, statistics varying from a percentage of zero to twenty of cures. Hysterectomy for cancer of the body of the uterus gives 75 per cent of cures. Dr. Noble reports thirty-two cases of hysterectomy for cancer. Ten of these have died of recurrence and one of pneumonia. Six cases have disappeared, two cases of cancer of the cervix have had recurrence, and the remaining thirteen are free from recurrence at the present time. The hope for improvement in results lies in early diagnosis. Dr. Noble strongly urges that all cases with irregular discharges should be promptly investigated.

Dr Frank E Hammond of Philadelphia read a paper entitled "The Value of Local Treatment in Gynecological Practice"

Dr F P Ball of Lock Haven presented a paper giving a report of a case of double extrauterine pregnancy, and emphasized the importance of early diagnosis.

Instrumental Perforation of the Uterus.—Dr. Wilmer Krusen of Philadelphia in this paper discussed the conditions which soften the uterus and render the accident liable—carcinoma, anæmia, tuberculosis, and subinvolution. The different perforations are enumerated with the results. He reported a case of perforation of the uterus at the fundus, in which the omentum had been caught by the curette and drawn through the uterus into the vagina. He saw the case within two hours after the accident, and immediately performed cœliotomy. An uninterrupted recovery ensued. He emphasized the necessity for care, cleanliness, and special training in all intrauterine manipulations.

Some Surprises Met in the Practice of Obstetrics.—Dr. R B. Ewing of West Grove reported a series of obstetric cases interesting from the fact that the unexpected occurred in their course. They were illustrative of the terse expression of one of the most gifted medical authors and teachers of America, after a lifetime of active service as an obstetrician, that "The practice of obstetrics is full of surprises"

Dr. John V. Shoemaker exhibited a patient with a peculiar parasitic disease of the skin. It was characterized by its appearance from the twentieth to the fortieth year in somewhat irregular patches upon the anterior portion of the chest. The cause, being from without the body, is one point in its dissimilarity to liver spots. The parasite is conveyed from water or from decayed vegetable material. Clean linen may contain the germs. In treatment, he especially stated that water should not be used; alcohol, or alcohol in water, being substituted; and, in medicaments, the copper salts, either in sulphate or oleate, and mercury in the form of ointment gave the best results.

A Remarkable Case of Infantile Typhoid of Fœtal Origin, with Recovery.—Dr. Harry C. Westervelt of Pittsburg reported the case of a woman seven months pregnant who had typhoid fever. Delivery occurred at seven months and the mother made a good recovery from the fever Weight of the child was nine pounds fourteen ounces, and it presented the characteristic "old man" appearance. A temperature of 103 4° F. soon appeared. Recovery ensued and the child presents every appearance of healthy babyhood.

The Effects of Typhoid Fever on the Nervous System.—Dr. C. C. Hersman of Pittsburg in this paper regarded as the most frequent causes of typhoid fever impure air, food, and water. The nervous system is usually the first attacked by the poison. Often, too, are the cardiac ganglion and nerve supply of the heart attacked. Meningitis is mentioned as a grave complication. Dr. Hersman had two such cases under his care within the past two years, one of which recovered. Friedlander of Berlin was quoted as giving 80 per cent. mortality in typhoid meningitis. Tubercular predisposition in children was considered a fruitful source of typhoid meningitis.

The Value and Importance of Teaching the Fundamental Branches of Medicine from the Standpoint of Their Practical Application.—This point was emphasized by Dr. Gwilym G. Davis of Philadelphia. The student should be so taught that he will understand his subject rather than simply memorize isolated facts. Textbooks are too statistical and not sufficiently explanatory. Ques-

tions which require an understanding of the subject for their answer should be given and not catch questions. The day of the true pedagogue, it was believed, was at last dawning.

Ruptured Tubal Gestation and the Physician.—Dr JOHN M. FISHER of Philadelphia, in a paper by this title, said that ectopic pregnancy was fraught with more immediate danger to the life of the individual than any other acute supravaginal disorder. None, however, it was stated, is more easy of diagnosis by the experienced gynecologist nor more easily dealt with. Prompt surgery, with but few exceptions, saves the patient. Almost always is the condition tubal. Causes and symptoms are given. The so-called conservative plans are not to be considered in successful treatment.

The Kidney Complications of Typhoid Fever.—Dr JAMES ELY TALLEY of Philadelphia presented this paper. Albuminuria, acute parenchymatous nephritis, hemorrhagic nephritis, and suppurative nephritis were mentioned as complications. Œdema is rarely produced and if the patient lives the nephritis almost never becomes chronic. Hemorrhagic nephritis is defined as but an aggravated form of acute parenchymatous nephritis. The tendency is toward uræmia and the mortality is large. Suppurative nephritis occurs occasionally, and in these cases typhoid bacilli have been found frequently in the pus or kidney substance at post mortem. If chronic nephritis exists and typhoid intervenes, the mortality is over 90 per cent. Albuminuria and acute nephritis, it is stated, occur in the typhoid fever of children with about the same frequency as in adults.

A New Method of Performing Nephropexy.—Dr HENRY BEYEA of Philadelphia in this paper described in full his method. The operation is indicated only where the pathologically mobile kidney produces a complexity of symptoms inducing persistent ill-health, and where the prescribed medical and mechanical treatment either fails to give relief, or is impracticable from the beginning.

Statistics of Typhoid Fever at the Philadelphia Hospital from January 1, 1897, to December 1, 1899.—Dr. HERMAN B. ALLYN in this paper gave in the whole number of one hundred and eighty-four cases a mortality of 16.86 per cent. This was governed largely by the character of the patients and the state of the disease at admission. The patients were of the neglected class. The causes of death, following Osler's classification, were: Asthenia, intercurrent affections, accidents of the lesion. In 88 per cent. of the last one hundred and thirteen cases the Gruber-Widal serum reaction was in accord with the final clinical diagnosis.

Dr. HOWARD FUSSEL of Philadelphia explained the value of the Tallquist Hæmoglobin Scale to the general practitioner.

Dr. THOMAS L. COLEY of Philadelphia read a paper entitled "Amyotrophic Lateral Sclerosis, with the Report of a Case."

Fracture of the Neck of the Femur.—Dr. CHARLES E. THOMSON of Scranton in this paper reported a case and exhibited an *x*-ray and specimen. The patient was sixty-two years of age and sustained a fracture in 1899; bedridden three months. Shortening amounted to two and one-half inches, and there was much pain in the hip. The operation was fully described. A solid silver nail three-sixteenths of an inch in diameter and two and one-half inches long was driven through the neck and into the femur. One year after, shortening was three-fourths of an inch, with 90 degrees free and painless motion. Death, six months later, occurred from intercurrent disease. The specimen showed firm bony union.

The Pathology, Symptomatology, and Treatment of Uræmia.—Dr. DAVID RIESMAN of Philadelphia read a valuable paper devoted to the portrayal of certain less common forms of uræmia—uræmic hemiplegia, and uræmic aphasia with mental confusion and insanity. Bleeding and sweating were emphasized in the treatment. The patient is put into a hot bath of 110° for ten minutes, and then into a hot pack for twenty minutes.

The Etiology of Acute Dysentery.—Dr SIMON FLEXNER of Philadelphia spoke briefly upon this subject. He said that reports of bacteriological work in the tropics, Japan, Germany, and in this country upon the etiology of acute dysentery agree that there is present a septic organism, quite peculiar and not found in the body under normal conditions, which seems to be present uniformly when cases of acute dysentery arise. It would appear that the sporadic cases have the same origin as the acute dysentery, which is of particular importance in the consideration of epidemics. The microorganism that has been discovered is that bearing more or less resemblance to the bacillus of typhoid fever. It occurs in the intestines and can be obtained from the dejecta. It does not occur in health or in other diseases. Moreover, the blood serum will give a reaction similar to the Widal reaction. Dr. Flexner thinks it probable that, as a result of this work, the septic organism of acute dysentery has been observed. It is possible by the use of this organism to produce serum which may be curative.

Dr Flexner's paper closed the scientific business. The new President, Dr F. P. BALL of Lock Haven, was introduced by the retiring President, Dr. Davis, and welcomed with a few happy remarks. After a brief address by Dr. Ball, Dr. ALEXANDER CRAIG of Columbia offered a resolution of thanks to all those participating in the arrangements for the pleasure and success of the meeting. The fifty-first annual meeting of the Medical Society of the State of Pennsylvania was then declared adjourned.

In the evening of the same day a special lantern-slide demonstration was given. Dr John G. Clark of Philadelphia exhibited "The Life History of the Ovary." Dr Richard M. Pearce of Philadelphia exhibited some of the histologic changes in diphtheria, selected from the illustrations in "The Bacteriology and Pathology of Diphtheria: a Study of 220 Fatal Cases," by W. T. Councilman, F. B. Mallory, and R. M. Pearce. The points demonstrated concerned the membrane, lesions in the lung, the heart, spleen, and lymph nodes, and the kidneys. Drs. George G. Ross and M. I. Wilbert of Philadelphia gave an exhibition of "Skiagraphy in Supposed Sprains." Dr Jay F. Schamberg of Philadelphia gave a representation of "The Various Types of Smallpox, with Remarks upon Differential Diagnosis." Dr M. K. Kassabian, in charge of the Rontgen Ray Laboratory and Instructor in Electro-Therapeutics in the Medico-Chirurgical College, gave an illustration of "Some Medical Uses of the *x*-Ray." Dr Kassabian spoke of the present knowledge in connection with the Rontgen rays, and of its diagnostic value in the detection of pathological conditions in the lung, pleura, heart, aorta, diaphragm, liver, stomach; also, in the examination of calculi and in affections of joints. He did not wish to be understood that former means of diagnosis should be disregarded, but to emphasize the fact that a new chapter had been opened in the diagnosis of diseases with the Rontgen Rays, and that the physician should resort to the latter in obscure cases.

An exhibition of "The Kromskop" was given by Mr. F. E. Ives of Philadelphia.

The Transformation of a Hypoacid Tuberculous Area into a Resistent Hyperacid and Arthritic Area.—Samuel Bernheim concludes from his study of the subject that tuberculous organisms are hypoacid and demineralized, while arthritic organisms are the direct opposite. To convert a tuberculous patient into an arthritic one, therefore, we should hyperacidify, mineralize, and phosphatize. The methods to be used are air, rest, and feeding, as hygienic measures, and the administration of the phosphate of creosote as a medicinal measure. This will cure the tuberculosis.—*Bulletin Médical de Québec.*

Croton Oil in one-sixth or one-eighth minim dose is a valuable purgative, without disagreeable effects.—Bond.

Guaiacol in local application is said, by a French writer, to remove pleuritic effusion and cure variocele and varix hydrocele.

Calcium Carbide acts in inoperable uterine carcinoma, by reason of the quicklime liberated by contact with water.—J. C. Chase.

Tapeworm.—Give a tea made from the flowers of reignonette, while fasting, and follow by a full dose of castor oil.—*La France Médicale.*

Iris Versicolor or irisin will cure sick-headaches, especially when it is accompanied by a sensation in the roof of the mouth as if it had a coating of cold grease.—Peraud.

Salicylates.—In consequence of the extraordinary activity of the kidneys in childhood, the salicylates may be given them in proportionately larger doses. A child of six years, for example, may be given without harm the dose of an adult.—*Peoria Medical Journal.*

Cystitis.—Treatment is the same, in the main, as for iritis, but mydriatics must be used with more caution. In some cases they may be harmful. If the pupil dilates freely suspend their use. If the tension of the eyeball becomes noticeably elevated the mydriatic should be stopped at once.—Edward Jackson.

Try Hyoscyamus in coma vigil; aconite and ipecac to abort croup; one in twenty solution of permanganate of potassium in toothache; strong hot coffee in uterine inertia; guaiacol as a local sedative; nitroglycerin in post-partum hemorrhage; potassium nitrate in snake bite; eupatorium for hiccough; polytrichium in ascites and anasarca; strychnine in colic.—*The Medical Summary.*

Constipation.—Green vegetables should be taken; fruit, especially apples (cellulose excites peristalsis), and marmalade are excellent for breakfast. Belladonna and nux vomica possess little value.

℞ Aloes socotrin. . . . . gr. i., ii., or iii.
Ferri sulph . . . . . gr. ¼.
Extract. hyoscyami . . . . gr. i.
Ft. pil. t. p. i. n.

The quantity of aloes requires readjustment, general reduction. Sometimes when a patient is impatient, one must give a drug and turn to adjuvants later. This should be done also in cases of atonic condition with dilated and loaded bowels. Salts and senna, caraway seeds, raisins, and figs are frequently very useful.—Sir James Sawyer.

Phosphorus.—When a person has swallowed a poison which is soluble in a fatty substance, as is phosphorus, milk hastens the development of disturbances. This is the case in some of the rat and vermin poisons with which many individuals attempt to commit suicide. In such, milk should not be used, but such substances as favor oxidation, such as turpentine, for example.—*Peoria Medical Journal.*

Adolescent Heart Strain is due to a want of muscular power of the cardiac muscles only, especially the musculi papillaries whose weakened condition permits of the regurgitant murmurs heard at the apex. The bruit present at the base is secondary to anæmia of the general system. Treatment should consist of rest in bed, seclusion, the administration of digitalis pushed until one has the physiological effects, and strychnine, preferably in the form of the tincture of nux vomica on account of its stimulating and appetizing properties.—Albert Martin, in *The New Zealand Medical Journal.*

Surgical Suggestions.

Foreign Body in the Ear.—Almost any object can be removed by syringing. A strong piston syringe is often required, but a high grade bulb syringe may answer. In obstinate cases put the canal on a stretch by pulling the ear firmly upward and outward while the stream is being forcibly injected.

Chloroform Anæsthesia.—A good guide to the condition of the circulation can be obtained from watching the color of the lips. A flagging circulation is early indicated by them. Patients, while on the operating table, die from one of three causes: (1) anæsthesia; 2) operation; (3) some accident. If death is due to the anæsthetic, it is due to an overdose, and this, in a very large proportion of cases, I believe, can and should be guarded against. The pupils give the first indication of danger. They dilate from one of two causes: (1) operating during incomplete anæsthesia; (2) the patient is getting an overdose. They dilate before respiration or the pulse give any indication of threatening trouble. Immediately I notice them commencing to dilate I remove the mask and let the patient have plenty of fresh air. So far, no satisfactory remedy for post-anæsthesia vomiting has been discovered. In the few cases I have been enabled to give oxygen with chloroform I have been greatly pleased, not only with the way in which the patient took it, but the vomiting was either nil or else very slight. The degree of anæsthesia in which we should leave our patients is a fruitful source of discussion. My practice is as follows: Dental operations.—Slight corneal reflex, post nasal just enough to keep the patient quiet. Lung operations.—Slight corneal reflex, dilatation of cervix and urethra complete. All abdominal operations complete. Brain operations and operations on tongue and jaw.—Slight corneal reflex.—W. B. VANCE, *Australian Medical Gazette.*

Surgical Hints.—Never give purgatives to children who have swallowed foreign bodies, for the reason that it is better that these should travel in company with fecal masses than by themselves.

Small boys brought to the surgeon with a very swollen penis nearly always have buried deep in a sulcus, and often invisible excepting by strict search, a ligature of some sort or a ring which must be removed.

In bad cases of burns or other severe and painful injuries, it is advantageous to give chloroform for the first dressing, or, at least, to give a hypodermic injection of morphine. This diminishes the pain and fear and consequently lessens the shock.

The parents of children with hypertrophied tonsils often object to operation because they think the latter may interfere with the child's voice. This fear is groundless. Explain to the parents that the voice will suffer more from the child's continued bad health than from anything else.

In children with prolapse of the rectum it will often be enough to prescribe the daily use of laxatives; to see that the bowels are moved only while the patient is lying down over a bed-pan, and to strap the buttocks tightly together, during the intervals between defecations, with a wide strap of adhesive plaster.

Diagnostic Aids.—Pruritus of the anus is frequently one of the early symptoms of prostatic disease. Sciatic neuralgia in females is often the result of ovaritis. Clubbed finger-tips are common in tuberculous and other wasting diseases. Morning sickness and loss of appetite for breakfast are common forerunners of consumption. Enlarged lymph-nodes of the neck in a child may be due to hypertrophied tonsils or to adenoid vegetations.—*Pennsylvania Medical Journal*, August, 1901.

Medical Items.

The Discovery of the Bacillus of Leprosy.—Dr. H. P. Lie, the present Director of the Leprosy Hospitals of Bergen, contributes an interesting biographical sketch of Dr. Gerhard Henrik Armauer Hansen to *Lepra*. Dr. Hansen was born in Bergen in 1841, and received his early education in the Cathedral College of that town. After passing his medical examinations, he became a resident in the Rigshospital of Christiania, and later spent some time as medical officer to the great Lofoten fisheries. In 1868 he became Assistant Medical Officer to the Bergen Leper Hospital, of which Dr. Daniel C. Danielssen was director. It was under the influence of this enthusiastic teacher and acute observer that Armauer Hansen began his life-long study of leprosy. His first investigation was to work out the significance of the so-called globi, or lepra cells, of Virchow. These bodies had been already referred to in 1840 by Danielssen, who thought they were characteristic of the disease. This idea he afterward gave up, and came to the conclusion they were the results of an involution process, that is, fatty degeneration. Hansen was not satisfied with the latter explanation; he thought that Danielssen's first idea was more likely the right one. This led him to investigate the matter, and in 1869 he published his results in a Norwegian periodical. At this time Hansen spent a year at various universities, but on his return to Norway he again applied himself to the difficulties which surrounded the etiology of leprosy. Various views were held at that time on this point. As a result of his observations and investigations, he published in 1872 an important paper, which gave rise to much discussion in Norwegian medical circles. His researches pointed to the contagious and specific nature of the malady. The Medical Society of Christiania voted a sum of money for him to continue his research. In the course of his journeyings through the country he came across instances of the disease which were more readily explained by contagion than by any other theory. An account of his additional investigation was published in the *Norsk Magasin for Lægevidenskaben*. Unfortunately, in 1874, this important contribution to the subject was but little known outside of Norway. His views confirmed those of Drognat-Landré, who had worked at leprosy in Surinam, and published a book entitled *La Contagion seule cause de la Lèpre* (Paris, 1860). This led Hansen to reinvestigate the peculiar bodies (globi-brown corpuscles) previously referred to, for he held that if the disease is contagious there must be some specific virus at work. His labors were rewarded by the discovery, in unstained preparations, of bacilli. These were ultimately stained, and are what we know them to be, the bacilli of leprosy. His discovery, be it noted, was made in 1873, that is about ten years before the bacillus tuberculosis was made known to the world by Koch. For years, Hansen has repeatedly tried to cultivate and inoculate the bacillus lepræ, which is also deservedly known as Hansen's bacillus, but up to the present fruitlessly.—*British Medical Journal.*

Marriage of the Deaf.—Professor E. A. Fay has examined the records of 4,500 marriages of the deaf, and he discovers that, while taking the marriages of deaf persons as a whole, nearly 9 per cent. of the offspring are deaf, as contrasted with less than ½ of 1 per cent. of deaf children as a result of the marriages of normal persons, a very different and much more favorable result is obtained if it be found that the deaf parents had no trace of previous deafness in their families. Marriage of deaf persons without deaf relatives is no more likely to result in deaf children than any marriage in the community at large, while marriage of hearing persons who have deaf relatives is just as likely to result in deaf children as the marriage of the deaf."—*Medical Review of Reviews.*

The "Human Monkey" of Java.—Professor Häckel's latest publication contains some curious information

about the "human monkey" of Java. An interesting specimen of the young gibbon was watched by Professor Hackel at his own house in Java. The species is found only in this island and is properly called *Hylobates leuciscus*. The natives call it "oa" on account of the characteristic sound it utters. When standing it is scarcely taller than a child of six. The head is comparatively small, and the waist is slender. The legs are short and the arms much longer. The face is more human than that of the orang-outang. Professor Hackel says: "Its physiognomy reminded me of the manager of an insolvent bank pondering with wrinkled brow over the results of a crash. Distrust of the 'oa' toward all white Europeans is very noticeable. On the other hand, he was on terms of intimate friendship with the Malays in our household, especially with the small children. He never crawled on all fours when tired of running, but stretched on the grass beneath the tropical sun, with one arm under his head. When I held tasty food just out of his reach he cried like a naughty child, 'huite, huite,' a sound altogether different from 'oa, oa,' with which he expressed various emotions. He had a third and more shrill sound when he was suddenly frightened. The speech of these human monkeys has not many different sounds, but they are modulated and altered in tone and strength with a number of repetitions. The animals also use many gestures, motions with their hands, and grimaces, which are so expressive in manner that a careful observer can detect their different wishes and various emotions. My specimen liked sweet wine. He grasped a cup in both hands and drank like a child. He peeled bananas and oranges just as we were accustomed to do, holding the fruit in his left hand. Most of the Malays do not regard the gibbon and orang-outang as brutes. They believe the former are bewitched men and the latter criminals who have been changed to monkeys as a punishment. Others think they are men in the course of metempsychosis."—*The Sun.*

An Investigation of Danyz's Virus.—Dr. M. J. Rosenau of the Marine Hospital Service has recently published an interesting bulletin recording the result of investigations carried on under his direction, with a view to discover the effect of the pathogenic microbe from which Danyz's virus is derived, as a destroyer of rats. Danyz's article on the subject appeared in the *Annales de l'Institut Pasteur* in April, 1900, a translation of which was given in the *Public Health Reports* for May 25, 1900. It goes without saying that if a really effectual means of destroying rats on a large scale can be worked out, plague will be, if not extirpated, at least checked to a very appreciable extent. Consequently, experiments of the nature of these undertaken by Dr. Rosenau, under the auspices of the Marine Hospital Service, possess an immense practical value. So far as the investigations concerning Danyz's virus are concerned, the conclusions arrived at by the workers of the Marine Hospital Service Laboratory can hardly be termed very encouraging. Its virulence has been raised and specialized by artificial means in the laboratory, so that it has become fatal for rats by ingestion. This artificial virulence is not very stable. It may be maintained under special conditions a few months, but the virulence is apt to fall off, especially on exposure to light and air. The effect upon rats depends somewhat on the amount ingested. Large amounts are quickly fatal. Small quantities are uncertain. Rats that survive the ingestion of the virus are rendered immune. In many respects, it resembles a chemical poison, with the great advantage that it is harmless to man and beast. However, it has the disadvantage of rendering animals immune by the ingestion of amounts that are insufficient to kill. The virus may, therefore, be used as one of the means in the fight against rats; but it is far from being a sure means of exterminating these rodents in a particular place.

Fresh-Air Work in New York City. The fresh-air work of this summer has been especially active. Of the larger agencies, says *Charities*, the Association for Improving the Condition of the Poor sends women and children for day excursions, and convalescent and ailing mothers and children for an average stay of two weeks to its summer home at Coney Island. The Charity Organization Society co-operates closely, providing an allotted number of persons on each day excursion, and referring those needing a stay of two weeks to the Association for Improving the Condition of the Poor. The St. John's Guild provides day excursions for sick or ailing children on its two floating hospitals, and furnishes extended treatment for children suffering from non-contagious diseases at its hospital on Staten Island. The fresh-air work of the Children's Aid Society benefits especially the children attending the various industrial schools of the society. Boys are sent to a large farm at Kensico, N. Y., and girls to a home at Bath Beach, where also the society maintains a home for convalescent or ailing women and children. The St. Vincent de Paul Society last year established a home at Baychester, N. Y., where parties of one hundred children are accommodated for twelve-day outings. The parties are made up through the various church conferences. The St. Vincent de Paul Society no longer secures through its agents, as in former years, two-week stays for tenement children in private homes in the country. A few parties, however, are arranged by correspondence, and sent through New York State and Pennsylvania, the Charity Organization Society providing Catholic children, and the *Tribune* Fresh-Air Fund the cost of transportation.

Formaldehyde Gas for Destroying Mosquitos.—Dr. M. J. Rosenau declares, in a recent issue of *Public Health Reports*, that experiments undertaken by him have shown that formaldehyde gas is an efficient insecticide so far as the mosquito is concerned. The experiments were all made upon the *Culex pungens*, and it was found that an exposure of three hours was invariably sufficient to kill all the mosquitos of this variety in a confined space, provided the gas was used in amounts usually employed for disinfection.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended October 5:

		Cases.	Deaths

THE CASE OF PRESIDENT McKINLEY.

THE following report has received the approval of, and is issued by, the undersigned, the medical staff attending the late President, William McKinley.

P. M. RIXEY.
MATTHEW D. MANN.
HERMAN MYNTER.
ROSWELL PARK.
EUGENE WASDIN.
CHARLES McBURNEY.
CHARLES G. STOCKTON.

October 12, 1901.

Surgical History.—President William McKinley was shot, by Leon F. Czolgosz, in the Temple of Music, at the Pan-American Exposition, Buffalo, N. Y., at about 7 minutes past 4 on the afternoon of Friday, September 6, 1901. Two shots were fired. One bullet struck near the upper part of the sternum, and the other in the left hypochondriac region. The President was immediately conveyed to the Emergency Hospital on the Exposition grounds by the motor ambulance, where he arrived at 4.18. Dr. G. McK. Hall and Mr. Edward C. Mann, medical student, of the house staff were in charge of the ambulance, Medical Student T. F. Ellis being the driver.

On arriving at the hospital, President McKinley was at once placed upon the table in the operating room and undressed. During the removal of his clothing a bullet fell out and was picked up by Mr. Ellis. Dr. Hall placed a temporary antiseptic dressing over the wounds, and Mr. Mann ordered a nurse to administer 0.01 gm. of morphine and 0.002 gm. of strychnine hypodermically.

Dr. Herman Mynter, who had been telephoned from police headquarters to report immediately at the Exposition Hospital, was the first surgeon to arrive, at 4.45 o'clock. At that time Drs. P. W. Van Peyma and Joseph Fowler of Buffalo and Dr. Edward Wallace Lee of St. Louis were present. Dr. Mynter brought with him Dr. Eugene Wasdin of the United States Marine Hospital Service.

Dr. Mynter inspected the President's wounds, and immediately saw their serious nature. He told the President that it would be necessary to operate, and at once set about making preparations, aided by the house staff and nurses and Dr. Nelson W. Wilson, Sanitary Officer of the Exposition, who at that time assumed charge of the hospital in the absence of Dr. Roswell Park, the Medical Director of the Exposition. The President's pulse on the arrival of Dr. Mynter was 84; he had no particular pain in the abdomen, and no apparent loss of liver dulness. He was evidently slightly under the influence of the morphine.

Dr. Matthew D. Mann arrived at the hospital at 5.10 P.M., having been telephoned for by Mr. John C. Milburn. He was followed, five minutes later, by Dr John Parmenter.

An examination was at once made, followed by a short consultation between Drs. Mann, Mynter, and Wasdin, which resulted in the decision to operate at once. The necessity for the operation was explained to President McKinley, and he gave his full consent. Immediate operation was decided upon because of the danger of possible continued internal hemorrhage and of the escape of gastric or intestinal contents into the peritoneal cavity, and because the President's pulse was getting weaker. Moreover, the daylight was rapidly failing. Dr. Roswell Park, who, by virtue of his office, had he been present would have performed the operation, was at Niagara Falls, and although a special train had been sent for him, it was uncertain when he would arrive.

Dr. Mann was selected to do the operation, with Dr. Mynter as his associate, by the common consent of the physicians present and at the request of Mr. Milburn, President of the Pan-American Exposition, who stated that he had been requested by President McKinley to select his medical attendants. Dr. Mann selected Drs. Lee and Parmenter as assistants.

At 5.20 Dr. Mann directed the administration of ether to President McKinley, and requested Dr. Wasdin to administer it. Ether was chosen as being, on the whole, the safer anæsthetic. While the anæsthetic was being given, the surgeons who were to take part in the operation prepared their hands and arms by thoroughly scrubbing with soap and water and immersing them in a solution of bichloride of mercury.

The operation began at 5.20. Dr. Mann stood upon the right-hand side of the patient, with Dr. Parmenter on his right-hand side. Dr. Mynter stood upon the left-hand side of the patient, and on his right was Dr. Lee. To Drs. Parmenter and Lee were assigned the duties of sponging and the care of the instruments. Dr. P. M. Rixey, U. S. N., President McKinley's family physician, having been detailed by the President to accompany Mrs. McKinley to the Milburn home, did not arrive until 5.30, when he gave very efficient service by guiding the rays of the sun to the seat of the operation by aid of a hand mirror, and later by arranging an electric light. Dr. Roswell Park arrived just as the operation on the stomach was completed, and gave his aid as consultant. Mr. E. C. Mann had charge of the needles, sutures, and ligatures. Mr. Simpson, medical student, was at the instrument tray.

The nurses, under the charge of Miss A. C. Walters, superintendent of the hospital, were Miss M. E. Morris and Miss A. D. Barnes, with hands sterilized: Miss Rose Baron, Miss M. A. Shannon, and Miss L. C. Dorchester, assistants, and Miss Katharine Simmons attending the anæsthetizer.

Besides those immediately engaged in the operation, there were present Drs. P. W. Van Peyma, Joseph Fowler, D. W. Harrington, and Charles G. Stockton of Buffalo, and Dr. W. D. Storer of Chicago.

The Operation.—President McKinley took the ether well, and was entirely under its influence in nine minutes after the beginning of the anæsthetization. The abdomen was carefully shaved and scrubbed with green soap, and then washed with alcohol and ether and the bichloride solution.

Inspection showed two wounds made by the bul-

lets. The upper one was between the second and third ribs, a little to the right of the sternum. The use of a probe showed that the skin had not been penetrated, but that the bullet had probably struck a button or some object in the clothing which had deflected it. The lower wound made by the other bullet—a 32 caliber—was on a line drawn from the nipple to the umbilicus. It was about half way between these points, and about 5 cm. to the left of the median line. A probe showed that this wound extended deeply into the abdominal walls, and that the direction was somewhat downward and outward.

An incision was made from the edge of the ribs downward, passing through the bullet wound and nearly parallel with the long axis of the body. A deep layer of fat was opened, and followed by incision of the fascia and muscles to the peritoneum. After cutting through the skin, a piece of cloth, undoubtedly a bit of the President's clothing, was removed from the track of the bullet, a short distance below the skin.

On opening the peritoneum, the finger was introduced and the anterior wall of the stomach palpated. An opening was discovered which would not quite admit the index finger. This opening was located near the greater curvature of the stomach, and about 2 cm. from the attachment of the omentum; its edges were clean cut and did not appear to be much injured.

The stomach was drawn up into the operation wound, and the perforation very slightly enlarged. The finger was then introduced and the contents of the stomach palpated. This was done to see if the stomach contained food, and also with the hope that possibly the bullet might be in the stomach. The stomach was found to be half-full of liquid food, but no evidence of the ball was discovered. In pulling up the stomach a small amount of liquid contents escaped, together with a good deal of gas. The tissues around the wound were carefully irrigated with hot salt solution and dried with gauze pads. The perforation in the anterior stomach wall was then closed with a double row of silk suture (Czerny-Lembert). The sutures were not interrupted with each stitch, but four stitches were introduced before the ends were tied. The loop was then cut off and the suture continued. About eight stitches were used in each row. The silk used was fine black silk, the needle being a straight, round sewing needle.

In order to examine the posterior wall of the stomach it was necessary to enlarge the incision, which now reached about 15 cm. in length. The omentum and transverse colon were pulled well out of the abdomen. The omentum was enormously thickened with fat and very rigid. In order to reach the back wall of the stomach, it was necessary to divide about 4 inches of the gastrocolic omentum, the cut ends being tied with strong black silk in two masses on each side. In this way the stomach could be drawn up into the operation wound, and the bullet wound in its posterior wall reached. This opening was somewhat larger than that in the anterior wall of the stomach, and had frayed and blood-infiltrated edges. Its exact location was impossible to determine, but it appeared to be near the larger curvature.

This opening was closed in the same way as the anterior wound, but with great difficulty, as the opening was down at the bottom of a deep pocket. A short curved surgical needle was necessary here. Little or no gastric contents appeared around this opening, but after it had been closed the parts were carefully irrigated with hot salt solution.

The operation on the stomach being now finished, Dr. Mann introduced his arm so as to palpate carefully all the deep structures behind the stomach. No trace of the bullet or of the further track of the bullet could be found. As the introduction of the hand in this way seemed to have a bad influence on the President's pulse, prolonged search for further injury done by the bullet or for the bullet itself was desisted from. The folds of the intestine which had been below the stomach were inspected for injury, but none was found. The entire gut was not removed from the abdomen for inspection, as the location of the wound seemed to exclude its injury. To have made a satisfactory search for wounds in the President's back, it would have been necessary to have entirely eviscerated him. As he was already suffering from shock, this was not considered justifiable, and might have caused his death on the operating table.

Before closing the abdominal wound, Dr. Mann asked each of the surgeons present, whether he was entirely satisfied that everything had been done which should be done, and whether he had any further suggestions to make. Each replied that he was satisfied. The question of drainage was also discussed. Dr. Mynter was in favor of a Mikulicz drain being placed down behind the stomach-wall. Dr. Mann, with the concurrence of the other surgeons, decided against this, as being unnecessary.

As the last step in the operation, the tissues around the bullet track in the abdominal wall were trimmed in order to remove any tissue which might be infected. The abdominal wound was then closed with seven through-and-through silkwormgut sutures drawn only moderately tight, the superior layer of the fascia of the rectus muscle being joined with buried catgut. The edges of the skin were brought together by fine catgut sutures. Where the bullet had entered there was slight gaping of the tissues, but it was not thought advisable to close this tightly, as it might allow of some drainage. The wound was then washed with hydrogen dioxid and covered with aristol powder and dressed with sterilized gauze and cotton, which were held in place with adhesive straps. Over all was put an abdominal bandage.

The President bore the operation very well. The time from the beginning of the administration of the anæsthetic until its discontinuance was exactly an hour and thirty-one minutes; the operation was completed at 6.50 P.M., having lasted from the time of the first incision, an hour and twenty-one minutes. At the beginning of the operation, President McKinley's pulse was 84. At 5.38, 0.002 gm. of strychnine was administered hypodermically. At 5.55 the respiration was 32 and the pulse 84—both good in character. At 6.00 the pulse was 88. At 6.20 it was 102, fair in character; respiration 30. At 6.22, 1.50 gm. of brandy was administered hypodermically. At 6.48 the pulse was 124, the tension good but quick; respiration 36. At 7.01, after the bandage was applied, the pulse was 122 and the respiration 32. At 7.17, 0.024 gm. of morphine was administered hypodermically.

At 7.32 the patient was removed from the hospital in the ambulance. Dr. Rixey asked Drs. Park and Wasdin to go in the ambulance, as his duty called him to go at once to inform Mrs. McKinley of her husband's condition and to prepare a room for his reception. Drs. Mann and Mynter, with friends of the President, followed in carriages immediately after. President McKinley had not then recovered from the anæsthetic. He bore the journey to Mr. Milburn's house exceedingly well, but it was found necessary to give him a small hypodermic injection of morphine during the transit, as he was becoming very restless. On arrival at the house of Mr. Milburn, 1168 Delaware Avenue, he was removed from

the ambulance on the stretcher and carried to a room in the northwest corner of the house, where a hospital bed had been prepared for him.

Remarks on the Operation by Matthew D. Mann, M.D. The difficulties of the operation were very great, owing partly to the want of retractors and to the failing light. The setting sun shone directly into the room, but not into the wound. The windows were low and covered with awnings. After Dr. Rixey aided us with a hand mirror, the light was better. Toward the end of the time a movable electric light with reflector was put in use. The greatest difficulty was the great size of President McKinley's abdomen and the amount of fat present. This necessitated working at the bottom of a deep hole, especially when suturing the posterior wall of the stomach.

The operation was rendered possible and greatly facilitated by a good operating table and the other appliances of a hospital, and by the presence of many trained nurses and assistants. Still, the hospital was only equipped for minor emergency work, and had but a moderate supply of instruments. Unfortunately, when called I was not told what I was wanted for, and went to the Exposition grounds entirely unprepared. Dr. Mynter had his large pocket-case, the contents of which were of great use.

As has already been noted, further search for the bullet was rendered inadvisable by the President's condition. The autopsy shows that it could not have been found, and that the injuries inflicted by the bullet after it passed through the stomach were of such a nature as to render impossible and unnecessary any further surgical procedure. A bullet after it ceases to move does little harm. We were often asked why, after the operation, we did not use the *x*-ray to find the bullet. There were several reasons for this. In the first place, there were at no time any signs that the bullet was doing harm. To have used the *x*-ray simply to have satisfied our curiosity would not have been warrantable, as it would have greatly disturbed and annoyed the patient, and would have subjected him also to a certain risk. Had there been signs of abscess-formation, then the rays could and would have been used.

My reason for not draining was that there was nothing to drain. There had been no bleeding nor oozing; there was nothing to make any discharge or secretion; the parts were presumably free from infection, and were carefully washed with salt solution. As there was no peritonitis and the abdomen was found post mortem to be sterile, we may safely conclude that no drainage could have been provided which would have accomplished anything. My experience teaches me never to drain unless there is a very decided indication for it, as a drain may do harm as well as good.

In conclusion, I wish to thank all the gentlemen who so kindly and skilfully assisted me. They were all surgeons of large experience in abdominal surgery, and their aid and advice were most valuable. Especially I wish to acknowledge my great obligation to my associate, Dr. Mynter. Not only was he an assistant, but he was much more, and helped me greatly by his skill and as a consultant, with his good judgment and extensive knowledge of abdominal work. Although called first, he waived his claim and generously placed the case in my hands, willingly assuming his share of the responsibility.

The anæsthetic was most carefully administered by Dr. Wasdin, and the knowledge that he had charge of this very important duty relieved me of any anxiety on that score.

In the eventful week that followed the operation Dr. Park and Dr. McBurney were towers of strength in helping to decide the many difficult questions which came up.

Dr. Rixey was in constant charge of the sick-room, aided later by Dr. Wasdin, who was detailed for this special duty. Both were unremitting in their care, and faithful to the end.

Dr. Stockton helped us in the last three days with the highest skill and best judgment.

Never, I am sure, under like circumstances, was there a more harmonious or better-agreed band of consultants. That our best endeavors failed was, I believe, no fault of ours; but it must be an ever-living and keen regret to each one of us that we were not allowed the privilege of saving so noble a man, so attractive a patient, and so useful a life.

The After-Treatment.—When put to bed the President was in fair condition. Pulse, 127; temperature, 100.6°; respiration, 30. The nurses on duty were Miss K. R. Simmons and Miss A. D. Barnes from the Emergency Hospital. Soon after his arrival, at 8.25, he was given morphine, 0.016 gm., hypodermically. There was slight nausea. The pulse soon improved. During the evening the patient slept at intervals, vomiting occasionally, but rallied satisfactorily. A slight discoloration of the dressings was noted at 10.45. There was occasional and slight pain. Ninety c.c. of urine was voided, and an enema of salt solution given and retained.

Second Day, Saturday, September 7.

After midnight the patient slept a good deal; he was free from pain and quite comfortable.

At 6 A.M., the temperature was 102°; pulse, 112; respiration, 24.

Gas in large quantities was expelled from the bowels. A saline enema was given as before. Miss Simmons and Miss Barnes were replaced by Miss Maud Mohan and Miss Jane Connelly. Miss E. Hurt of San Francisco, Cal., Mrs. McKinley's nurse, also rendered assistance, and Miss Grace Mackenzie of Baltimore, Md., arrived September 9, and was detailed for regular duty. P. A. Elliott, J. Hodgins, and Ernest Ulmeyer of the U. S. A. Hospital Corps were detailed as orderlies.

During the forenoon 0.21 gm. of morphine was administered hypodermically.

At 1.15 P.M. a saline enema of 500 c.c. was given. As the pulse was rising, 0.30 gm. of fluid extract of digitalis was injected hypodermically.

The President rested quietly until 6.30 P.M., when he complained of intense pain in the pit of the stomach, and was given 0.008 gm. morphine sulphate hypodermically. He was very restless, but after being sponged rested again.

At 6.30 P.M., the pulse was 130; temperature 102.5°; respiration, 20.

During the day the digitalis, morphine, and saline enemas were kept up at regular intervals; 4 gm. of sanatose was added to the water at 10.30 P.M. At 11.15 P.M. the President passed from the bowels 240 c.c. of a greenish colored fluid and some particles of fecal matter.

The total amount of urine for 24 hours was 970 c.c.

Quantity	[illegible]
Color	[illegible]
Reaction	[illegible]
Urea	[illegible]
Albumin	[illegible]
Phosphates and [illegible]	[illegible]
Sugar	[illegible]
In bean	[illegible]

[illegible] centrifuge showed a great amount of large and small epithelial cells with some [illegible] and casts, many [illegible]. There is a comparatively large number of hyalin casts, [illegible] small [illegible] granular [illegible]

occasional fibrinous one. The amount of sediment is large for the quantity of urine submitted. There were no crystals in the sediment.

Third Day, Sunday, September 8.

During the early morning the President slept a good deal, but was restless, and at times coniused and a little chilly. On the whole, he passed a fairly good night.

He expelled a little gas and brown fluid from the rectum. The digitalis was continued, and at 7.45 A.M. 0.002 gm. of strychnine was given hypodermically. At 8.20 A.M. he was clear and bright, with the pulse strong and of good character.

The wound was dressed at 8.30, and found in a very satisfactory condition. There was no indication of peritonitis. Pulse, 132; temperature, 102.8°; respiration, 24.

The dressing on the wound was changed because there was some exudation. The bullet track was syringed out with hydrogen dioxide. There was very little foaming, and there were no signs of pus.

At 10.40 A.M., following an enema of Epsom salts, glycerin, and water, he had a small stool with gas, and another at noon. He was less restless and slept a good deal.

At noon Dr. Charles McBurney joined the medical staff in consultation, having been summoned by Dr. Rixey.

Bulletin 14, 12 *m.*—The improvement in the President's condition has continued since the last bulletin. Pulse, 128; temperature, 101°; respiration, 27.

During the day he continued to improve; he slept four or five hours and his condition was satisfactory.

At 4.45 P.M., he was given a teaspoonful of water by the mouth; also an enema of sweet oil, soap, and water. He passed slightly colored fluid with some little fecal matter and mucus. After this he had a small quantity of water by the mouth, and at 6.20 P.M. a nutritive enema of egg, whiskey, and water, which was partly retained. Digitalis and strychnine were both given during the evening.

At 9 P.M., the President was resting comfortably. The pulse was 130; temperature, 101.6°; respiration, 30.

Four hundred and twenty c.c. of urine was passed during the day.

Second Uranalysis.

Quantity	450 c.c.
Color	amber, slightly turbid
Reaction	strongly acid
Specific gravity	1.026
Urea	0.038 gm. per 1 c.c. of urine
Albumin	mere trace
Sugar	none
Indican	abundant
Sulphates	increased
Phosphates	somewhat increased
Chlorides	somewhat increased

Microscopic Examination.—Microscopic examination of sediment obtained by centrifuge shows fewer organic elements. Some large and small epithelial cells and some leukocytes. Casts are not so abundant as yesterday and are *principally* of the small finely granular variety. There is a marked diminution in small renal epithelial cells.

Quite a quantity of large crystals of uric acid and bacteria are present.

Fourth Day, Monday, September 9.

The bulletin tells the story of the fourth day.

Bulletin 17, 6 *a.m.*—The President passed a somewhat restless night, sleeping fairly well. General condition unchanged. Pulse, 120; temperature, 101°; respiration, 28.

Bulletin 18, 9.20 *a.m.*—The President's condition is becoming more and more satisfactory. Untoward incidents are less likely to occur. Pulse, 122; temperature, 100.8°; respiration, 28.

Bulletin 19, 3 *p.m.*—The President's condition steadily improves and he is comfortable, without pain or unfavorable symptoms. Bowel and kidney functions normally performed. Pulse, 113; temperature, 101°; respiration, 26.

Bulletin 20, 9.30 *p.m.*—The President's condition continues favorable. Pulse, 112; temperature, 101°; respiration, 27.

Codeine was substituted for morphine, as the pain was less. Digitalis and strychnine were stopped. Nutritive enemas were given at 3.20 A.M., at 4.30 and 10 P.M. Hot water was taken quite freely by the mouth.

Attempts to get a good movement of the bowels were successful at noon, when he had a large light-brown, partly formed stool. This followed a small dose of calomel and a high enema of oxgall.

On the whole, the President's condition improved steadily during the day. He slept a good deal and was fairly comfortable. There was no pain on pressure over the abdomen.

Third Uranalysis.

Quantity received	540 c.c.
Color	amber, slightly turbid
Specific gravity	1.026
Albumin	a trace
Indican	not so abundant as yesterday
Urea	0.047 gm. per c.c. of urine
Chlorides and phosphates	about normal
Sulphates	still somewhat high
Sugar	none

Microscopic Examination.—Microscopic examination of sediment obtained by centrifuge shows a decrease in the amount of organic elements and an increase of amorphous urates, but fewer crystals of uric acid. Casts are fewer and only the small granular and large hyaline varieties. The proportion of casts is greater. There are very few epithelial cells, mostly of renal type. A large number of cylindroids are found.

Fifth Day, Tuesday, September 10.

Soon after midnight the President had a high enema of soap and water, which was expelled, together with some fecal matter. He took hot water frequently, and slept a good deal.

Bulletin 21, 5.20 *a.m.*—The President has passed the most comfortable night since the attempt on his life. Pulse, 118; temperature, 100.4°; respiration, 28.

On awaking he felt very comfortable, and his mind was clear and cheerful. The nutritive enemas were kept up, and water given by the mouth. Had two small stools during the day. The only medicine given was one hypodermic of codeine phosphate, 0.015 gm.

In the evening the dressings were examined, and as there was considerable staining from the discharge, it was thought best to remove four stitches and separate the edges of the wound. A little slough was observed near the bullet track, covering a space nearly an inch wide, the thickness of the flaps. The separation seemed to extend down to the muscle. The surfaces, except those mentioned, looked healthy, but not granulating. It was supposed that the infection of the wound occurred either from the bullet or from the piece of clothing carried into the wound at the time of the shooting. The parts were thoroughly washed with hydrogen dioxide and packed lightly with gauze, and held together with adhesive straps.

Sixth Day, Wednesday, September 11.

Bulletin 26, 9 *a.m.*—The President rested comfortably during the night. Decided benefit has followed the dressing of the wound made last night. His stomach tolerates the beef juice well, and it is taken with great satisfaction. His condition this morning is excellent. Pulse, 116; temperature, 100.2°.

Bulletin 27, 3.30 *p.m.*—The President continues to gain, and the wound is becoming more healthy. The nourishment taken into the stomach is being gradually increased. Pulse, 120; temperature, 100.2°.

Bulletin 28, 10 *p.m.*—The President's condition continues favorable. Blood count corroborates clinical evidence of the absence of any blood poisoning. He is able

to take more nourishment and relish it. Pulse, 120; temperature, 100.4°.

The blood count made by Dr. Wasdin in the evening was as follows:

Leucocytes	6,752
Red cells	3,920,000

A little after midnight Wednesday morning, the patient was given 4 c.c. of beef juice, the first food taken by the stomach. It seemed to be very acceptable. Nutritive enema was given at 2 A.M.; later there was a yellow stool.

From 4 to 8 c.c. of beef juice was given every one to two hours during the day. The rectum was becoming irritable, and did not retain the nutritive enemas well.

At 10 A.M. the remaining stitches were removed, the wound separated and dressed. It seemed to be doing well. Most of the sloughing tissue had separated.

The patient slept much during the day, and expressed himself as feeling very comfortable. The only medicine administered was one hypodermic of strychnine.

In the evening he was changed to a fresh bed. Nutritive enemas were continued.

Urine was passed much more freely—750 c.c. in twenty-four hours.

Fourth Uranalysis.

Quantity	82 c.c.
Color	amber, clear
Specific gravity	1.027
Reaction	strongly acid
Albumin	a trace
Indican	abundant
Urea	0.04 gm. per 1 c.c. of urine
E. phosphates and chlorides	normal
Sulphates	still a little high

Microscopic Examination.—Microscopic examination of sediment obtained by centrifuge shows a marked diminution in amount of organic elements, but a great increase in uric-acid crystals.

There are very few epithelial cells—mostly of renal type.

There are fewer casts—small and large hyaline—some finely granular.

Cylindroids are more abundant.

Seventh Day, Thursday, September 12.

The President slept a good deal during the night, and awoke in the morning feeling better. The beef juice was continued and increased, and a little chicken broth added to the dietary. He also had a little whiskey and water.

At 8.30 A.M. he had chicken broth, a very small piece of toast and a small cup of coffee. He did not care for the toast, and ate scarcely any of it.

The wound was dressed and washed with a weak solution of iodine and then with hydrogen dioxide. He was given 30 c.c. of castor oil at 9.20 A.M.

The President now seemed at his best and his condition to warrant the favorable prognosis given out. The time for peritonitis and sepsis had passed. The bowels had moved and gas passed freely, showing that there was no obstruction. The tongue was clear, and the appetite increasing; and he seemed to be able to digest food. There was no pain nor tenderness in the abdomen, and he was able to turn easily and to sleep on his side. The urine was steadily increasing. His spirits were good and his mind clear, while his pulse, though frequent, was strong and of good quality, and the temperature low.

The analysis of the urine gave no uneasiness, as the amount of urea was fair; there was no albumin worth considering, and the casts were rapidly diminishing. There were no more of them than are found in a large percentage of cases following a long operation under ether. The excess of indican was taken to mean merely some intestinal indigestion, and to be of no serious import. The only symptom to cause any uneasiness was the frequency of the pulse. Still anxiety on this score was relieved by knowing that the President had naturally a rapid pulse, and that it was easily excited. The open wound was not considered important. It looked healthy, and, although it would take a long time to heal, in itself it was evidently causing no harm, nor was it likely to.

Dr. McBurney left Buffalo for his home in the morning, having arranged to return at once if his presence was desired.

Toward noon it was noticed that the character of the pulse was not quite so good. Infusion of digitalis, 8 c.c., was ordered, and strychnine, 0.002 gm.

It was thought probable that there was some intestinal toxæmia, as there had been no free movement from the bowel since food had been begun, the oil having failed to act. Gradually the pulse went to 130, and grew weaker.

Dr. Charles G. Stockton was added to the medical staff in consultation. At 7 P.M. the President was given 0.20 gm. of calomel.

Bulletin 32, 8.30 p.m.—The President's condition this evening is not quite so good. His food has not agreed with him, and has been stopped. Excretion has not yet been properly established. The kidneys are acting well. His pulse is not satisfactory, but has improved in the last two hours. The wound is doing well. He is resting quietly. Temperature, 100.2°; pulse, 128.

At 9.30 P.M. a second dose of 30 c.c. of castor oil was given, followed by a high enema of oxgall. This resulted in a large, dark semifluid stool, which seemed to exhaust him somewhat. Stimulants were given freely. No more beef juice or food was given. The pulse grew rapidly worse, but at midnight there seemed some improvement, as bulletin 3 shows. At 11 P.M. 420 c.c. of normal salt solution was given subcutaneously.

Bulletin 33, 12 m.—All unfavorable symptoms in the President's condition have improved since the last bulletin. Pulse, 120; temperature, 100.2°.

Fifth Uranalysis.

Quantity	132 c.c.
Color	light amber, very turbid
Specific gravity	1.025
Reaction	acid
Albumin	mere trace, if any
Indican	less
Urea	0.044 gm. per 1 c.c. of urine
Sulphates	about normal
E. phosphates	much increased
Chlorides	normal

Microscopic Examination.—Microscopic examination of sediment obtained by centrifuge shows fewer organic elements than the last examination. There is less uric acid and a large amount of amorphous phosphates. Renal casts, about as in the last examination, with very few cylindroids.

Eighth Day, Friday, September 13.

At midnight the pulse was fairly good, 132. Strychnine and whiskey were given at intervals, and hypodermics of camphorated oil.

Bulletin 34, 2.50 a.m.—The President's condition is very serious, and gives rise to the gravest apprehension. His bowels have moved well, but his heart does not respond properly to stimulation. He is conscious. The skin is warm, and the pulse small, regular, easily compressible, 126; respiration, 30; temperature, 100°.

The wound had been dressed regularly in the manner described three times a day. At 9 A.M. the dressing was changed, and a mixture of balsam of Peru and glycerin put in on gauze after the douching.

Stimulants were continued as before, but more freely. Coffee, 45 c.c., and clam broth, 60 c.c., were given; also liquid peptonoids.

At 8.30, 1.50 gm. of adrenalin was given hypodermically, and repeated at 9.40.

At 10 A.M., nearly two pints of normal salt solu-

tion was given under the skin, and one pint containing adrenalin at 6 P.M. Nitroglycerin and camphor were also injected, at various times together with brandy and strychnine.

Stimulants as detailed above were used freely all day.

3.30 P.M. Pulse growing weaker.

5.00 P.M. Oxygen given and continued for some hours.

6.30 P.M. Last bulletin, No. 39

Bulletin 39, 6.30 *p.m.*—The President's physicians report that his condition is most serious in spite of vigorous stimulation. The depression continues and is profound. Unless it can be relieved, the end is only a question of time.

At 6.35 P.M., and again at 7.40, morphine was given hypodermically, as he was very restless and seemed to be suffering.

9.00 P.M. Heart sounds very feeble.

Microscopic Examination.—Microscopic examination of sediment obtained by centrifuge, before and after clearing, shows no change from yesterday's sample. Casts, hyaline and granular, both large and small, comparatively few. Cylindroids, a few. Crystals, large amount of uric acid, some sodium urate, and in the untreated specimen a large amount of amorphous deposit, principally of phosphates. There are a few epithelial cells, small, granular. Occasional red cells and leukocytes.

REPORT ON THE AUTOPSY[1]

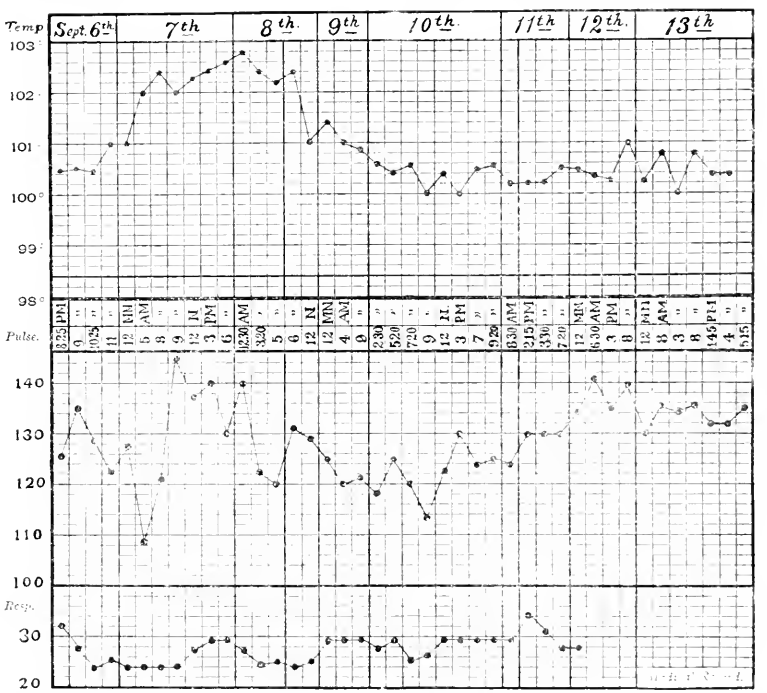
BY HARVEY R. GAYLORD, M.D.,

Pathologist and Director of the New York State Pathological Laboratory.

Ordinary signs of death: ecchymosis in dependent portions of the body. Rigor mortis well marked. Upon the surface of the chest, to the right of the midsternal line, a spot 1 cm. in diameter, dark-red in color, with a slight crust formation covering it, 5.5 cm. from the suprasternal notch; from the right nipple, 10 cm.; from the line of the right nipple, 8.25 cm. Surrounding this spot, at which point there is an evident dissolution of the continuity of the skin, is a discolored area of oval shape extending upward and to the right. In its greatest length it is 11 cm., and in its greatest width, 6 cm. It extends upward in the direction of the right shoulder. The skin within this area is discolored, greenish-yellow and mottled.

The surface of the abdomen is covered with a surgical dressing, which extends down to the umbilicus and upward to just below the nipples. The innermost layer of cotton is covered or stained with Balsam of Peru and blood. On removing this dressing, a wound, parallel to, and somewhat to the left of, the median line, is exposed, inserted in which are two layers of gauze, likewise impregnated with balsam of Peru. The wound is 14.5 cm. in length and is open down to the abdominal muscles. The layer of abdominal fat is 3.75 cm. in thickness. The appearance of the fat is good, a bright yellow in color. No evidence of necrosis or sloughing. In the left margin of the surgical wound, lying 1 cm. to the right of a line drawn from the umbilicus to the left nipple 15.5 cm. from the nipple and 10.5 cm. from the umbilicus, is a partly healed indentation of the skin, and an excavation of the fat immediately beneath it (this is the site of the entry of the bullet), extending down to the peritoneal surface. On making the median incision, starting from the suprasternal notch and extending to a point just below the

[1] The autopsy was performed by Drs. Gaylord and Mynter.



The President continued to sink, becoming weaker and weaker.

At 10.00 P.M., the oxygen was discontinued. The heart sounds were very feeble and consciousness lost.

The President died at 2.15 A.M. September 14.

Drs. E. J. Janeway and W. W. Johnston, who, at the request of Dr. Rixey, had been summoned in consultation, arrived too late, but were present at the autopsy. Dr. McBurney also returned on Friday afternoon.

Analysis of Urine.

Color	amber, turbid, with phosphates
Quantity	252 c.c.
Reaction	acid
Specific gravity	1.025
Albumin	mere trace, if any
Urea	3.647 gm. per 100 c.c.
Indican	a trace
Phosphates	increased
Chlorides	normal
Sulphates	a little high

symphysis, the subcutaneous fat is exposed, which is of bright yellow color and normal appearance except in an area which corresponds superficially to the area of discoloration described as surrounding the wound upon the chest wall. This area marks the site of a hemorrhage into the subcutaneous fat. The remainder of the subcutaneous fat is firm and measures 4.75 cm. in thickness on the abdominal wall. On opening the sheath of the right rectus muscle, it is seen to be of dark-red color. (Culture taken from ecchymotic tissue under the upper bullet hole and from between the folds of the small intestine. Three tubes from each locality on agar and gelatin.

On opening the abdominal cavity, the parietal surface of the peritoneum is exposed, and is found to be covered with a slight amount of bloody fluid; is perfectly smooth and not injected. The great omentum extends downward to a point midway between the umbilicus and the symphysis. It is thick, firm, its inferior border is colored by coming in contact with the intestines. Below the umbilicus a few folds of intestines are exposed. These are likewise covered with discolored blood, after the removal of which the peritoneal surface is found to be shiny. On the inner aspect of the abdominal wound the omentum is found to be slightly adherent to the parietal peritoneum, and can be readily separated with the hand from the edge of the wound. At this point the omentum is somewhat injected. This adhesion to the omentum is found to extend entirely around the abdominal wound. The parietal peritoneum immediately adjacent to the inner aspect of the abdominal wound is ecchymotic.

On removing the subcutaneous fat and muscles from the thoracic wall, the point which marks the dissolution of continuity of the skin upon the surface is found to be directly over the margin of the sternum and to the right side between the second and third ribs. There is no evidence of ecchymosis or injury to the tissues or muscles beneath the subcutaneous fat. On making an incision through the subcutaneous fat, directly through the wound upon the chest, a small cavity is exposed about the size of a pea, just beneath the skin, which is filled with fluid blood. The subcutaneous tissue underlying the area of discoloration on the surface of the chest wall shows hemorrhagic infiltration.

On removing the sternum, the lungs are exposed, and do not extend far forward. A large amount of pericardial fat is exposed. Pleural surface on both sides is smooth. There are no adhesions on either side within the pleural cavities. The diaphragm on the right side extends upward to a point opposite the third rib in the mammary line. No perceptible amount of fluid in either pleural cavity. On opening the pericardial cavity, the surface of the pericardium is found to be smooth and pale. The pericardium contains approximately 6 cc. of straw-colored, slightly turbid fluid. (Some taken for examination.)

On exposing the heart, it is found covered with a well-developed panniculus. The heart measures, from the base to the apex, on the superficial aspect, 12.5 cm. The right ventricle is apparently empty. The heart feels soft and flaccid. On opening the left ventricle, a small amount of dark-red blood is found. The muscle of the left ventricular wall is 1.5 cm. in thickness; dark reddish-brown in color; presents a shiny surface. The average thickness of the pericardial fat is 3.5 mm. (Cultures made from the auricle.) The left auricle contains but a small amount of dark currant-colored blood. The mitral valve admits three fingers. The right ventricle, when incised in the anterior line, is found to be extremely soft; the muscular structure is 2 mm in thickness. The panniculus measures 7 mm. The muscle is dark red in color; very shiny, and the pericardial fat invades the muscular wall at many points.

On opening the right auricle, it is found to be filled and distended by a large currant-colored clot, which extends into the vessels. The tricuspid orifice admits readily three fingers. The coronary arteries are patulous and soft; no evidence of thickening.

Lungs are gray color, and contain a moderate amount of coal-dust pigment. Slight amount of frothy fluid escapes from the bronchi; but the pulmonary tissue is crepitant and free from exudate.

On unfolding the folds of intestine, there is no evidence of adhesion until a point just beneath the mesocolon is reached, when, on removing a fold of small intestine, a few spoonfuls of greenish-gray thick fluid flows into the peritoneal cavity.

On the anterior gastric wall is an area to which a fold of the gastrocolic omentum is lightly adherent. On breaking the adhesion there is found a wound about midway between the gastric orifices, 3.5 cm. in length, parallel with the greater curvature of the stomach, 1.5 cm. from the line of omental attachment. This wound is held intact by silk sutures. There is no evidence of adhesion at any other point on the anterior wall. The gastric wall surrounding the wound [illegible] to a distance of 2 cm. to 3 cm. is discolored dark greenish gray in appearance, and easily torn. On exposing the posterior wall of the stomach from its adhesions along its greater curvature, the omentum is found to be slightly adherent, a line of silk ligatures along the greater curvature of the stomach marking the site where the omentum had been removed. On throwing the omentum downward, the posterior gastric wall is exposed. On the posterior wall, a distance of 2 cm. from the line of omental attachment, is a wound approximately 2 cm. long, held intact by silk sutures. The gastric wall surrounding this wound is discolored. On the surface of the mesocolon, which is posterior to the gastric wall at this point, is a corresponding area of discoloration, the portion coming directly in contact with the wound in the gastric wall being of dull gray color. The remainder of the surface of the posterior wall of the stomach is smooth and shiny. Beyond the surgical wound in the posterior wall of the stomach is found an opening in the peritoneal fat, large enough to admit two fingers. This opening communicates with a track which extends downward and backward as far as the finger can reach. The tissues surrounding this track are necrotic. On removing the descending portion of the colon, a large irregular cavity is exposed, the walls of which are covered with gray, shiny material, and in which are found fragments of necrotic tissue. Just at the superior margin of the kidney is located a definite opening, which forms the bottom of the track traced from the stomach. On stripping the left kidney from its capsule, it is found that the superior portion of the capsule is continuous with the cavity. The weight of the left kidney is 5 oz. 1 gm. The kidney is readily stripped from its capsule, is dark red, the stellate veins are prominent, and along its greater curvature are numerous dark red depressions. On the superior aspect of the kidney is a protrusion of the cortex, dark red in color, and in this protrusion is a laceration 2 cm. long, extending across the superior border, approximately at right angles to the periphery of the kidney and from it directly backward. On incising the kidney, the cortex and medulla are not easily distinguishable from one another, both are of reddish color, the cortex measuring approximately 9 mm. in thickness. The vessels in the pyramids of Ferrein are very prominent. Beneath the protruding portion of the surface the cortex is dark red in color. This discoloration extends downward in pyramidal form into the medulla. The laceration of the surface marks the apex of the protrusion of the kidney substance. Between the spleen and the superior aspect of the kidney is a necrotic tract which extends down and backward, and ends in a blind pocket. The tract which included the superior aspect of the kidney can be traced into the perinephritic fat to a point just above the surface of the muscles of the back.

The necrotic cavity which connects the wound on the posterior wall of the stomach and the opening adjacent to the kidney capsule is walled off by the mesocolon, and is found to involve an area of the pancreas, approximately 45 mm. in diameter and extending about half-through the organ. This organ at its center forms part of the necrotic cavity. Through its body are found numerous minute hemorrhages and areas of gray softening, the size of a pea or smaller. These are less frequent in the head portion of the pancreas.

A careful examination of the track leading downward toward the dorsal muscles fails to reveal the presence of any foreign body. After passing into the fat, the direct character of the track ceases, and its direction can be traced no further. The adjoining fat and the muscles of the back were carefully palpated and incised, without disclosing a wound or the presence of a foreign body. The diaphragm was carefully dissected away, and the posterior portion of the thoracic wall likewise carefully examined. All fat and organs which were removed, including the intestine, were likewise examined and palpated without result.

The great amount of fat in the abdominal cavity, and surrounding the kidney rendered the search extremely difficult.

The right kidney is imbedded in a dense mass of fat; capsule strips freely; it weighs 5 oz., measures 11 cm.; cut substance is soft; cortex is 6 mm. in thickness; pyramids in color; cut surface slightly dulled. There are a few depressions of the surface, and the stellate veins are prominent.

The liver is dark-red in color, the gall-bladder distended. The organ was not removed.

The autopsy continued for a longer period than was anticipated by those who had charge of the President's body, and we were requested to desist seeking for the bullet and terminate the autopsy. As we were satisfied that nothing could be gained

by locating the bullet, which had apparently set up no reaction, search for it was discontinued.

Anatomic Diagnosis.—Gunshot wound of both walls of the stomach and the superior aspect of the left kidney; extensive necrosis of the substance of the pancreas; necrosis of the gastric wall in the neighborhood of both wounds; fatty degeneration, infiltration, and brown atrophy of the heart muscle; slight cloudy swelling of the epithelium of the kidneys.

A matter of no inconsiderable embarrassment to us arose in the objection to our removing sufficient portions of the tissues for examination. We were able to secure only two small fragments of the stomach wall; tissue from around the wound upon the chest wall; a portion of fat from the wall of the necrotic cavity; a small piece of each kidney, that of the left kidney including the portion involved by the original wound; and pieces of heart-muscle from the right and left ventricles. The microscopic examination of these tissues follows:

The piece of retroperitoneal fat, where it forms part of the necrotic cavity, is seen on section to be covered with a thick gray deposit, which has an average thickness of from 4 mm. to 6 mm. Beneath this, and separating it from the fat, is a well-defined area of hemorrhage from 1 mm. to 2 mm. in thickness. The appearance of this piece of tissue is characteristic of the fat tissue surrounding the entire cavity. A section made perpendicular to the surface and stained with hematoxylin-eosin shows the following characteristics: Under low power there is no evidence of round-celled infiltration between the fat cell or of fat necroses. The surface of the tissue which, in the microscopic specimen, was covered by a layer of grayish material, proves, under low power, to consist of a partly organized fibrinous deposit. At the base of this deposit is evidence of an extensive hemorrhage, marked by deposits of pigment. The surface of the membrane is of rough and irregular appearance, and contains a large number of round cells with deeply stained nuclei. Under high power the organization of the membrane may be traced from the base toward the surface. The portion immediately adjacent to the fat tissue consists of a network of fibrin inclosing large numbers of partly preserved red blood corpuscles. In many areas the red blood corpuscles are broken down and extensive deposits of pigment are found. Extending into the fibrin structure of the membrane are numerous typical fibroblasts and round cells. In some regions, pigment is evidently deposited in the bodies of large branching and spindle cells. Here and there, included in the membrane, are the remains of fat cells, and toward the surface of the membrane a large number of round cells scattered through the interstices of the membrane. There are but few polymorphonuclear leukocytes. Here and there in the membrane are fragments of isolated fibrous connective tissue with irregular contours and an appearance suggesting that they are fragments of tissue which have been displaced by violence and included in the fibrin deposit. The fibrin in the superficial layers of the membrane is formed in hyaline clumps. The organization along the base of the deposit is comparatively uniform.

Sections stained with methylene blue, carbol-thionin, and Gram's method were carefully examined for the presence of bacteria, with negative results. Even upon the surface of the membrane there are no evidences of bacteria.

The section of the left kidney, including the triangular area of hemorrhage described in the macroscopic specimen, reveals the following appearances: (Section hardened in formalin, stained with hæmatoxylin-eosin.) Examined macroscopically, section represents a portion of a kidney cortex made perpendicular to the surface of the cortex, and including an area of hemorrhage into the substance of the cortex 1 cm. in length, measured from the capsular surface downward, and presenting a width of from 5 mm. to 6 mm. The capsular surface has apparently been torn.

Under low power the margins of the preparation are found to consist of well-preserved kidney structure. There is a slight amount of thickening of the interstitial tissue, and occasional groups of tubules are affected by beginning cloudy swelling. The glomeruli are large, and present a perfectly normal appearance. As we approach toward the center of the preparation, occasional glomeruli are met with in which the capillary loops are engorged and the adjacent tubules contain red blood-corpuscles. A short distance further, the kidney structure becomes entirely necrotic. Here and there the remains of tubules may be made out, and these are infiltrated with cells. The necrotic area presents a rough, net-like structure. As we approach toward the surface of the kidney, we find that the necrosis becomes more marked. There is the merest suggestion of kidney structure, its place being taken by disintegrated red blood-cells and leukocytes, embedded in a well-defined fibrinous network. There is great distortion of the kidney structure about the periphery of the necrotic area. In this region a considerable amount of pigment is also found in the necrotic tissues.

Under high power, the characteristics of the necrotic tissues may be better observed. The kidney structure is broken up and torn into irregular fragments, infiltrated by red blood corpuscles and leukocytes. In the portion of the necrotic mass beneath the capsule, the kidney structure is practically obliterated, and is replaced by a network of fibrin, which includes large numbers of red blood-cells and leukocytes. Scattered through the entire necrotic area are frequent deposits of pigment.

In the deeper portions of the necrotic area, the margins of the fibrin deposit are invaded by fibroblasts from the connective-tissue structure of the kidney. The organization in these areas is, however, slight.

Sections stained with methylene-blue and Gram's method and carefully examined under oil immersion, fail to reveal the presence of any organisms. In preparations stained with methylene-blue, the deposits of pigment may be readily observed. Section of the same tissue hardened in Hermann's solution and examined for fat, shows the presence of numerous fat droplets within the epithelium of the tubules which are adjacent to the area of necrosis. In the portions of the preparation more widely distant from the area of necrosis, no fat is present.

Section of the right kidney hardened in formalin and stained with hematoxylin-eosin reveals the presence of areas in which slight parenchymatous degeneration of the epithelium in the uriniferous tubules may be noted. These areas are not extensive, and are confined to single groups of tubules. The interstitial connective tissue of the organ seems to be slightly increased in amount, but there is no well-defined round-celled infiltration. An occasional hyaline glomerulus is to be met with in these cases surrounded by increased connective tissue. The epithelium of the kidney tubules, aside from these in which the parenchymatous degeneration is present, is well preserved. The nuclei are well stained; protoplasm, finely granular.

A fragment of the stomach wall taken from the immediate neighborhood of the anterior wound is in a condition of complete necrosis. The nuclei of the cells are scarcely demonstrable. The epithelial surface is recognized with difficulty. At its base are apparently a few round cells. Examination of the blood-vessels reveals nothing characteristic. There is apparently no evidence of thrombosis. A section made through the gastric wall at some distance from the wound reveals the well-preserved muscular structure of the gastric wall, which presents no characteristic alterations. Superficial portions of the epithelium have apparently been affected by post-mortem digestion. However, in one portion of the preparation, the epithelium is intact, and shows distinct evidence of marked round-celled infiltration between the glandular structures. The blood-vessels contained blood corpuscles with the usual number of leukocytes.

The fragments of heart-muscle which were removed from the right and left ventricular walls were examined in the fresh state, and exhibited a well-defined fatty degeneration of the muscle fibers, and in the case of the right ventricular wall an extensive infiltration between the muscle fibers, of fat, was apparent. Sections from these fragments of muscle hardened in Hermann's solution are taken for examination. A fragment of muscle from the right ventricular wall was removed at a point where the fat penetrated deeply into the muscular structure, the ventricular wall at this point showing an average thickness of 2.5 mm. Under low power, the muscle fibers are separated into bundles by masses and rows of deeply stained fat cells. The muscle fibers are seen to contain groups of dark brown granules lying in the long axes of the cells. Under high power, these are resolved into extensive groups of dark brown pigment arranged around the nuclei. The muscle fibers are slender, the cross and longitudinal striation is well defined. Examined near the margin of the preparation, where the osmic-acid fixation has been successful, all of the muscle fibers are found to contain minute black spherical bodies, extending diffusely through all the muscle fibers about the entire margin of the preparation. These fine fat droplets are present in sufficient amount to speak of an extensive diffuse fatty degeneration of the muscle fibers. Where the large fat cells have separated the muscle fibers, these are found to be more atrophic than those in the central portions of the larger bundles.

The examination of the section through the healed bullet wound on the chest walls reveals nothing of importance. The dissolution of continuity is filled in by granulation tissue, and there is evidence of beginning restoration of the epithelium from the margins. Stains for bacteria give negative results.

In summing up the macroscopic and microscopic findings of the autopsy, the following may be stated: The original injuries to the stomach-wall had been repaired by suture, and this repair seems to have been effective. The stitches were in place, and the openings in the stomach-wall effectually closed. Firm adhesions were formed upon the anterior and posterior walls of the stomach, which reinforced these sutures. The necroses surrounding the wounds in the stomach do not seem to be the result of any well-defined cause. It is highly probable that they were practically terminal in their nature, and that the condition developed as a result of lowered vitality. In this connection there is no evidence to indicate that the removal of the omentum from the greater curvature and the close proximity of both of these wounds to this point had any effect in bringing about the necrosis of the gastric wall, although circulatory disturbances may have been a factor. The fact that the necrotic tissue had not been affected by digestion strongly indicates that the necrosis was developed but shortly before death. The excavation in the fat behind the stomach must be largely attributed to the action of the missile. This may have been the result of unusual rotation of a nearly spent ball, or the result of simple concussion from the ball passing into a mass of soft tissues, Such effects are not unknown. The fact that the ball grazed the superior aspect of the left kidney shown by the microscopic investigation of that organ, indicates the direction of the missile, which passed in a line from the inferior border of the stomach to the tract in the fat immediately superior to the kidney. There was evidence that the left adrenal gland was injured.

The injury to the pancreas must be attributed to indirect, rather than direct, action of the missile. The fact that the wall of the cavity is lined by fibrin, well advanced in organization, indicates that the injury to the tissues was produced at the time of the shooting. The absence of bacteria from the tissues indicates that the wound was not infected at the time of the shooting, and that the closure of the posterior gastric wound was effectual. The necrosis of the pancreas seems to us of great importance. The fact that there were no fat necroses in the neighborhood of this organ indicates that there was no leakage of pancreatic fluid into the surrounding tissues. It is possible that there was a leakage of pancreatic fluid into the cavity behind the stomach, as the contents of this cavity consisted of a thick, grayish fluid, containing fragments of connective tissue. In this case the wall of fibrin would have been sufficient to prevent the pancreatic fluid from coming in contact with the adjacent fat. The extensive necrosis of the pancreas would seem to be an important factor in the cause of death, although it has never been definitely shown how much destruction of this organ is necessary to produce death. There are experiments upon animals on record, in which the animals seem to have died as a result of not very extensive lesions of this organ. One experiment of this nature reported by Flexner (*Journal of Experimental Medicine*, Vol. II) is of interest. The fact that concussion and slight injuries of the pancreas may be a factor in the development of necrosis is indicated by the researches of Chiari (*Zeitschrift für Heilkunde*, Vol. XVII, 1896, and *Prager med. Wochenschr.*, 1900, No. 14), who has observed (although a comparatively rare condition) extensive areas of softening and necrosis of the pancreas, especially of the posterior central portion which lies directly over the bodies of the vertebra, where the organ is most exposed to pressure or the effects of concussion. The wound in the kidney is of slight importance, except as indicating the direction taken by the missile. The changes in the heart, as shown by the macroscopic inspection and the microscropic examination, indicate that the condition of this organ was an important factor. The extensive brown atrophy and diffuse fatty degeneration of the muscle, but especially the extent to which the pericardial fat had invaded the atrophic muscle fibers of the right ventricular wall, sufficiently explain the rapid pulse and lack of response of this organ to stimulation during life.

REPORT ON THE BACTERIOLOGIC EXAMINATION.

BY HERMAN G. MATZINGER, M.D.,

Bacteriologist to the New York State Pathological Laboratory.

It is obvious that the short space of time which has elapsed since the death of the President has hardly been sufficient to prepare a complete and thorough bacteriologic report. This report contains all the observations which have been made up to this time:

On September 11, during the life of the President, cultures were made by Dr. Wasdin from the base of the abdominal wound and from the dressings removed at the same time. These were submitted to me for examination, and showed the presence of the ordinary pus organisms: Staphylococcus pyogenes aureus and S. cereus albus, with a gas-forming bacillus which, in pure anærobic culture on glucose gelatin, forms small, pearly, translucent colonies, with no liquefaction. In litmus milk it produces acid, but no coagulation. Morphologically, it is apparently a capsulated, short bacillus, which takes stains poorly, and which does not stain by Gram's method. Inoculated into the ear vein of a rabbit, which was killed immediately afterward, it produced, after twenty-four hours in the body of the rabbit, a marked accumulation of gas in the organs, and again grew out in pure culture. As yet the organism is not fully identified.

None of these cultures showed streptococci. A bacterium which appears to be one of the proteus group was, however, isolated, which does not stain by Gram, and appears in varying forms, sometimes small oval, and again quite rod-shaped and in short chains. Sometimes it is surrounded with a slimy covering, which remains clear like a capsule when the organism is stained. On slanting agar, it produces a whitish, slimy growth, which gradually runs to the bottom of the slant and produces an odor of decomposition On gelatin, it grows very slowly with slight and slow indication of liquefaction. In litmus milk, it produces acid and rapid coagulation.

At the time of the autopsy, September 14, inoculations were made by myself. From the base of the wound there was again obtained a number of pus organisms, principally a white staphylococcus and the bacterium described above, but no streptococci. Cultures made from the peritoneal surface of the intestines were entirely negative. Cultures made from the under surface of the omentum near the colon were entirely negative, both with and without oxygen. Cultures from the blood of the right auricle were likewise negative. A very careful and extensive search for microorganisms in the contents of the necrotic cavity behind the stomach reveals nothing but a short stumpy bacterium which, as far as the work has been carried at present, appears to belong to the proteus group, and is very like Proteus hominis capsulatus, described by Bordoni and Uffreduzzi.

Morphologically it is not uniform, and sometimes appears almost encapsulated, being surrounded by material that does not stain; is quite refractory to Gram, and produces an odor of decomposition as it grows. It does not liquefy gelatin rapidly and grows slowly, as a glistening white elevated surface growth which slowly sinks; but on agar in the thermostat it grows very rapidly as a moist, grayish-white, translucent mass. Colonies on gelatin plates have a clean circumference, are granular and quite refractive. In litmus milk it produces acid and rapid coagulation. Animal experiments are still incomplete, and cannot be published at this time.

It must be stated that there is occasion for suspecting that this may be a contamination, either from the outer wound or elsewhere, because, quite unavoidably, the technic of obtaining the material and cultures from the necrotic cavity was not absolutely correct.

Cultures made from the small area of the broken-down tissue under the chest wound at the time of the autopsy

grew what appears to be Staphylococcus epidermidis albus, described by Dr. Welch.

The slimy, gray necrotic material from the cavity above the transverse mesocolon behind the stomach was carefully examined microscopically, with the result that very few microorganisms were found in the fresh state, and no recognizable tissue elements of any kind, no leukocytes or pus-corpuscles, but an abundance of crystals which appeared more like fatty acid than fat crystals. It contained no free hydrochloric acid, and was alkaline in reaction. Experiments as to its digestive power were negative. About 2 cc. of this material was injected into the space behind the stomach of a dog (still living), with no results except quite an elevated temperature for three or four days. Other animal experiments are also still incomplete.

It might be well to state here that the bacteriologic examination of the chambers and barrel of the weapon used, as well as the empty shells and cartridges, ordered by the District Attorney, was entirely negative, except that from a loaded cartridge there was grown an ordinary staphylococcus and a mould. The chemical examination of the balance of the loaded cartridges, made by Dr. Hill, chemist, was also negative.

The absence of known pathogenic bacteria, particularly in the necrotic cavity, warrants the conclusion that bacterial infection was not a factor in the production of the conditions found at the autopsy.

FAILURE OF THE KNIFE IN THE TREATMENT OF CANCER.

By ROBERT REYBURN, A.M., M.D.,
DEAN, PROFESSOR OF HYGIENE AND PREVENTIVE MEDICINE, MEDICAL DEPARTMENT HOWARD UNIVERSITY, WASHINGTON, D. C.

FOR many years the writer advocated the thorough removal of all cancerous tumors by the knife. In the recent years of his professional career, however, the discouraging fact of the almost invariable return of these tumors, after being operated upon, has greatly modified his views as to the benefits to be derived from these operations.

The following opinions of authorities will show that other surgeons have had similar experiences: Dr. J. M. Baldy of Philadelphia, in a paper read at the last meeting of the American Medical Association, says that only 5 per cent. of the patients operated upon for cancer of the cervix uteri are cured. He further states that the statistics of the operations at Johns Hopkins Hospital give the same result.[1] In an abstract of the views of P. G. Unna on the subject of cutaneous cancer,[2] we find that he recommends the use of the Paquelin cautery as a substitute for the knife. This is generally used superficially, singeing the parts only. He states that he has observed a checking of the malignant process, and the appearance of granulation tissue. Herzfield[3] says that abdominal hysterectomy for uterine cancer is a failure, for the cellular tissue and lymph glands cannot be removed. Vaginal hysterectomy, he says, is only palliative in 50 per cent. of the cases operated upon; it is, however, absolutely without danger, and in the remaining cases lasting results are obtained.

At the Ninth German Congress of Gynecology, held at Giessen May 29-31, 1901, Professor W. A. Freund said that he was able to report only two cases of cancer of the uterus permanently cured by surgical operation in twenty-three years of experience. He learned by inquiry in the various clinics of Germany that the average mortality after abdominal extirpation with removal of the larger portion of the parametrium and the glands, is 24½ per cent., and with a record of 46½ per cent. of recurrences during the first year.[4]

Dr. Cyrus A. Kirkley[5] at the last meeting of the American Gynecological Society, May 30 to June 1, 1901, said that the only indication for abdominal hysterectomy was when the cancer was strictly confined to the cervix and body of the uterus, or to the body alone. Electro-cauterization, as practised by Dr. Byrne, was given the preference over all other methods of operating.

In an editorial[6] note occurs the following: "Carcinoma of the uterus and its treatment has been the subject of thorough discussion in the American and German gynecological societies during the past few weeks. All the reports in regard to the treatment and recurrence are most melancholy and unsatisfactory."

An article by Dr. C. Trunecek[7] on the mechanism of the arsenical treatment of malignant tumors is commented on as follows: "He now announces that carcinoma or sarcoma cells are directly necrosed by the action of the arsenic, and their protoplasm is coagulated. The stroma cells become degenerated and exudation follows, which in turn produces further changes in the tumor cells. Inflammation with demarkation is the result of the application of arsenic to the surrounding sound tissue. It gradually passes into a suppurative stage, terminating in the throwing off of the entire necrosed tumor as a foreign body. In short, the organism reacts to the arsenical tumor as to a foreign body, and throws it off. The tumor when left alone does not induce any reaction of this nature; the organism makes no effort to defend itself against it, and is in turn destroyed by it."

The universal use by all surgeons of the principles of aseptic surgery has rendered the operations for cancer so comparatively safe that surgeons have been tempted to prevent the recurrence of these tumors by extending the field of their operations. So extensive are the mutilations now recommended by some authors for the removal of cancerous tumors, especially of the uterus and its appendages, that it would seem doubtful whether we ought not to describe the operation as one of the removal of the patient from the tumor rather than that as one of the removal of the tumor from the patient.

What does this show? It seems to me that it is a virtual confession of the failure of the knife in the cure of these cases, in that we are extending more and more our incisions into the apparently healthy tissues, in order to prevent this recurrence. Admitting, therefore, for the sake of argument, that the use of the knife has been a failure in these cases, what is the reason for it?

After a prolonged study of this subject the following explanation has suggested itself to me, as seemingly conclusive on this point. When we make an incision into any part of the body for the removal of a malignant growth, we at once divide and lay wide open for infection every vein and lymphatic vessel in the part operated upon. No matter what we may believe to be the contagium of cancer, the fact remains the same. Dr. Lambert Lack of England believes that cancer is produced by an abnormal development taking place in normal or healthy epithelium, when invading the lymph spaces of the body.

[1] *Journal American Medical Association*, June 8, 1901, pp. 1650 and 1664.
[2] *Ibid.*, July 6, 1901, p. 60.

[6] *Ibid.*, July 13, 1901, p. 46.
[7] *Journal American Medical Association*, July 6, 1901, p. 74.

In confirmation of this theory, he adduces the results of his experiments with rabbits and other animals. In a number of cases by introducing healthy epithelium into the abdominal cavities of rabbits, he succeeded in developing cancerous tumors.[8]

Dr. Konstantinowitch[9] succeeded in producing growths not dissimilar from granuloma, and containing epithelioid and giant cells, by inserting spores of lycopodium under the skin. Dr. Harvey Gaylord and others assert, on the other hand, that cancer is produced by the growth in the body of a living organism—a protozoon.

Whatever theory we may adopt as to the causation of cancer, there are two facts in its history that seem to be now generally admitted. The first of these is that it is probably always local in its early stages, and the second is that its origin is due to an injury or local irritation of the part affected. If we believe that the recurrence of cancer in cases operated upon is due to infection through the medium of the divided veins and lymph channels, the question arises, Can we supplement the knife, or substitute for it any other plan for removing these tumors that will prevent this systemic infection?

It is the belief of the writer that this can be done by adding to, or substituting for, the knife the electric cautery, the thermo-cautery, or, in a limited number of cases, the use of arsenic or chloride of zinc for the removal of the morbid growths. The marvelously successful results of Dr. John Byrne of Brooklyn in the treatment of uterine cancer show clearly that the removal of uterine cancer by the electric cautery is, by far, the best method of treatment.

In his first series of 367 cases published in 1889, Dr. Byrne shows the unparalleled result of not having a single death occurring during this vast series of operations. He shows another significant fact, namely, that the average length of life of patients, after being operated upon in this manner, far exceeds that found in those operated upon by the knife. The manner in which the statistics of the results of operations by the knife for uterine cancer are given in our textbooks and medical journals makes it very difficult to form an intelligent opinion; but after careful examination of many of them it is the deliberate opinion of the writer that the average length of life of the patients who have undergone hysterectomy, partial or complete, for this disease is no greater than that of those who have not been operated upon. The average length of life of patients (untreated) with uterine cancer is from two to two-and-a-half years, and it is very doubtful whether any long series of cases can be shown in which the average length of life has been to any appreciable extent increased by hysterectomy.

For this reason, therefore, I would advocate the entire abandonment of hysterectomy, partial or complete, for patients afflicted with cancer of the uterus. It seems to be clearly shown by Dr. Byrne that the operation recommended by him is far superior to hysterectomy; and now let us try to study out the reasons for it. The first reason for the superiority of this operation is that it is absolutely aseptic. While we do not expect sepsis in modern surgical operations, yet in a limited number of these cases sepsis does, unfortunately, occur, and this danger is entirely eliminated by the use of the electric cautery. A very significant fact is noted by Dr. Byrne in his history of these operations, and this is that, when the disease does recur in these cases, it rarely occurs in the cicatrices produced by the action of the electric cautery on the tissues.

[8] MEDICAL RECORD, Sept. 2, 1899, p. 345.

[9] *Philadelphia Medical Journal*, June 8, 1901, p. 1067.

What does this show? It certainly seems to prove that the vitality of the contagium (whatever it may be) has been destroyed and rendered harmless. Not only is this the case, but the destructive action of the cautery has caused a layer of lymph to be thrown around the cancer cells, which probably protects the healthy tissues, and prevents the future absorption of the cancerous materials into the system. This protective power of a layer or zone of lymph surrounding pathogenic microorganisms is often a source of protection to the body in disease.

Take, for instance, the phenomena found in lupus. Lupus is generally admitted to be a disease of the skin produced by the invasion of the tubercle bacillus. Yet, how different is the history of a case of lupus from that of a case of pulmonary tuberculosis. Cases of lupus are often chronic in character, and may exist for many years without seriously impairing the health of the patient. The writer had a patient under his care who had suffered from this disease for ten years, and was still able to do manual labor. The irritation produced by the tubercle bacilli at the site of the lupus (of the face and neck) had produced a layer of lymph around the tuberculous nodules, and, encasing them, had prevented systemic infection. The same conditions are found to exist in the tuberculous glands, so-called strumous glands of the neck, in scrofulous persons. These tuberculous deposits may remain latent for an indefinite length of time without any apparent injury to the body. If, however, they commence to break down and show a tendency to suppurate, then—the protective layer of lymph which had prevented the absorption of the bacilli or their toxins being removed—absorption may take place, and general tuberculosis result.

The objection may be urged against Dr. Byrne's method of operating that it is not applicable for the removal of cancers of the breast, or of large cancerous tumors occurring in other parts of the body. If the theory advocated in this paper be correct, then it would seem eminently proper that in such cases the electric cautery or thermo-cautery should follow the knife. In other words, immediately after the tumor has been removed in the usual manner by the knife, and the surface of the wound of operation has become thoroughly dried, and all hemorrhage being arrested, the seat of operation should be thoroughly seared by the electric or thermo-cautery.

The beneficial effects in preventing recurrence resulting from the use of arsenic and chloride of zinc for the removal of superficial cancers are also applications of the same principles advocated in the above paper. The arsenic and chloride of zinc produce layers of lymph under and around the former seat of the cancer, which prevent further infection. Finally, the writer would remark that, having only recently taken up this method of treatment, the time is as yet too short for him to give, from his own experience, any statistics that would be of value. He can only say that so far the results are exceptionally good, and he hopes that others besides himself will take up this method of treatment for cancer, and especially for cases of cancer of the uterus.

Some Coughs Produced Outside the Chest.—W. N. Robertson has found the cause of cough often referable to other organs than those in the chest. His experience includes coughs due to intestinal and gastric parasites, foreign bodies in the ear, enlarged turbinates, hysteria, enlarged tonsils and uvula, tumor of the epiglottis, fleshy bands in the pharynx, etc. Contrary to experience of most practitioners, he has not found enlarged lingual tonsil to be a cause of cough.—*Australasian Medical Gazette.*

REPORT OF THE SUMMER WORK OF THE MILK COMMISSION OF THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

By HENRY DWIGHT CHAPIN, M.D., Chairman.

It may be of interest to the members of the society briefly to rehearse the incidents leading up to the formation of a milk commission before speaking of its work. A year and a-half ago an evening was devoted to a discussion of the milk problem, especially in connection with large cities. A number of experts were present, including the Chief of the Dairy Division of the United States Department of Agriculture. The subject seemed one of such importance, and so much interest was aroused, that the society determined to form a commission that should study the best methods of improving the milk supply of New York. The time seemed ripe for such a movement, as the interest aroused and the success of the work have since proven. Moreover, the Medical Society of the County of New York, as the public and legal representative of the medical profession, and the guardian of the city's health, seemed the proper body to undertake such a work.

The first meeting of the commission was devoted to a discussion of the problem and how it might best be approached. The milk that is put into a large city must be gathered from diverse and distant sources, transported many miles, and finally distributed, after many vicissitudes and changes, to the customer, who himself keeps it a certain length of time, under possibly unfavorable conditions, before its use. When we consider that all this happens to a vital fluid that is unstable in its composition, that is sensitive to many unavoidable factors, such as temperature, atmospheric effects, shaking, and, above all, to dirt and dirty utensils, the complexity of the question may be appreciated. Heretofore most of the work done in a public study of a city's milk supply has concerned itself principally with the chemical ingredients of milk, more particularly the amount of butter fat it contains.

One of the members of the commission, having studied this subject for several years, found that the milk of New York, especially as supplied by the best dealers, runs fairly high in butter fat. While the law requires 3 per cent., an examination of over twenty samples from diverse sources showed an average of about 4 per cent. to be present, and not infrequently 5 per cent. is reached by the best dairies. Further examination showed that much was to be desired in point of cleanliness of the milk. Milk is an exceedingly good culture medium for the growth of bacteria of all kinds, and modern studies show that the presence and numbers of bacteria form a good gauge of the general condition of the milk, and the care with which it has been handled. The proper preservation of milk is also involved, as it is well known that the deterioration of milk from acid changes is due to bacterial growth. Ordinary bacteria that contaminate and grow luxuriously in milk come from the dirt that follows a careless handling of the milk anywhere from its first production to its delivery. It seemed well to the commission to establish an advanced standard of clean milk for the ordinary dealer, and the index of cleanliness would be established by a bacterial count. In other words, a bacterial standard would be applied as a gauge of the condition of milk. As this work was to be entirely voluntary, as far as the dealers were concerned, it was decided to invite them to a conference with the commission, and learn their ideas as to the feasibility of the undertaking. Accordingly, 180 invitations were sent out to dealers in Manhattan and The Bronx, this including all those of any financial importance, as shown by their commercial ratings. The meeting was held on November 16 at the Academy of Medicine, and about fifty dealers were present. They were invited to give their views freely as to whether part of their milk could not be put out according to an advanced standard for the benefit of infants, invalids, or any who desired a superior article. While many practical difficulties were urged, the general sense of the meeting seemed to be that with some extra care and expense many improvements could be made, under proper guidance, in putting out a strictly clean milk. Encouraged by this expression of opinion, as well as by the good will and spirit shown by the dealers, the commission determined to call a second meeting of those who were willing to have their milk examined and certified by the commission. In the meantime a series of suggestions adapted from the dairy rules of the United States Department of Agriculture were combined in a circular, together with a tentative standard adopted by the commission. The final paragraph explains the latter as follows:

"The Milk Commission of the New York County Medical Society agrees to guarantee or certify the milk of all dealers desiring such certificate. A special label will be furnished for this purpose. The standard required to obtain this endorsement will be that the acidity must not be higher than 2 per cent., and that the milk must not contain more than 30,000 germs, or bacteria of any kind, to the cubic centimeter. This will be tentatively adopted as a standard of clean milk, as bacteria get into the milk through lack of cleanliness during the milking and careless handling of the milk after the milking, and hence is a good clue to the care bestowed in the production and general handling of milk. The milk, before testing, must be in its natural state, not having been heated and without the addition of coloring matter or preservatives. The butter fat must reach 3.5 per cent. Examination must be made by the experts retained by the commission, with a frequency at their option, according to the season and the general condition of the milk under inspection, and at least once a month. The commission reserves the right to change its standard, in any reasonable manner, upon due notice being given to the dealer. The expense of the examination will be met by the dealer. All reports of examinations will be strictly confidential between the commission and the individual dealer."

About fifteen dealers attended the second meeting, which was understood to include all who were at that time willing to work with the commission. A report was then made to the Comitia Minora, who authorized the continuance of the work along these lines. The first examination was made March 4, for certification, the count showing 58 500 with butter fat 3 per cent. It may be of interest here to see how the better grades of milk in New York run in bacteria. The following tests furnished by Dr. Park will show the amount of bacterial contamination of milk put into New York, during a winter and a summer day. The first was taken November 19, 1900, being a mild winter day; temperature during the afternoon was 70°, and of the night 50° F. Samples of milk taken from carts received directly from cars gave an average temperature of about 52° F., the range being from 50° to 58°. The number in the six samples ran as follows: 56,000; 128,000; 35,000; 256,000; 13,600; 2,880,000. For a summer day, June 29, 1901, was taken, the day temperature being 90° F., and the night temperature 78° F. Six samples taken at random show as follows: 520,000; 30,000,000; 3,530,000; 12,000,000 210,000,000; 9,600,000.

Some idea of the extent of the bacteriological work upon milk done for the commission will be appreciated by stating that from March 4 to the present date, 800 separate bacteriological examinations have been made. This laborious undertaking has been accomplished by Dr. Sarah Belcher, to

whose zeal and enthusiasm much of the success of the work is due. The commission is also greatly indebted to Dr. Park for valuable oversight and advice, and to the Rockefeller Institute for Medical Research for its co-operation in allowing Dr. Belcher to render these services as part of the work of the institute. Bacterial tests have been made in the Research Laboratory of the Department of Health. After visits to a number of farms and dairies, it was aimed to classify the various sources of contamination, so that each one might be separately inspected and eliminated as the cause of trouble, or corrected, if found at fault. In order to reduce to practical results these bacterial researches, the following factors were considered and carefully studied:

1. Condition of barn.
2. Condition of cows.
3. The milkers.
4. Condition of utensils.
5. Processes of cooling.
6. Transportation.
7. Condition of cans or bottles when returned from city.

1. Condition of Barn.—Dirt and dust that are usually so abundant in an average barn readily get into the stream of milk or pail, and form a fruitful source of bacterial contamination. The common sources of dust are the hay-loft overhead, cobwebs on walls and ceiling, loose boards, dirty windows, floors of dirt, unclean manure-gutters, excessive bedding, storage of grain or feed in the barn, the rations, such as piles of hay placed near the milking, and the storage of farm or other utensils in the barn that soon become covered with dust. A dirty barn quickly raises the bacteria in milk there collected. Thus, on June 8, a cow was milked in such a barn and an examination of the milk showed 120,000 bacteria to c.c. At the same day and hour, another cow in the same apparent condition was milked in the adjoining pasture, away from the dust of the barn, the milk here showing only 26,000. This experiment repeated twenty times in various localities, always gave similar results. There is invariably a large increase of bacteria in milk collected in a dirty barn. Even when a barn has been cleaned up, some source of dust may be overlooked and cause trouble. Thus, on June 15, premises were examined after the barn had been cleaned, as well as the cows. Twelve cows standing in a row in the barn all showed a low bacterial count in the milk separately examined, except the one at the end, which showed 1,000,000. This cow stood next to a pile of dry feed, which was the only factor to account for the contamination. Here was explained an aberration in the milk of this barn that we could not at first understand, as everything had been cleaned according to directions, but this little detail was overlooked. Many visits and experiments have thus shown contamination that can easily be avoided if the source is discovered.

2. Condition of Cow.—Much dirt that gets into milk comes directly from the cow. When the cow is being milked the udder is pulled down, which loosens dandruff, hairs, and dirt from all the adjacent parts. Particular sources of impurity that are apt to be overlooked in cleaning a cow are the folds between the udder and the flanks and dirt on the tail. Fifty bacterial tests were made in direct relation to the cow. The following will serve as an example, in which clean barns and milkers figured in connection with dirty cows. Four dirty cows under above conditions gave an average count of 90,000. Four other cows from the same herd, in the same barn, were carefully cleaned and then milked by the same man, giving an average count of only 2,000.

3. The Milker.—A fruitful source of dirt is directly attributed to the milker. The dirt may come from the hair, hands, especially when chapped and scaly, finger nails, tobacco, or clothing. It was found that the milk from certain men always gave a high bacterial count that could invariably be traced to some of the above-mentioned sources. It is better to have the milkers clean-shaven, and, when milking, they should be clad in white duck suits or blue overalls that are frequently washed. Young single men make the best milkers, as they are less apt than married men to carry infection from the home. The details of their living admit of better oversight.

4. The Utensils.—These include pails, strainers, condition of creamery or dairy room, aerators, stationary vats, portable vats, and bottles or cans. It is sometimes difficult to find which of these factors is at fault, but the condition of the pail or strainer is very important, as, when they were found at all dirty, the bacteria count was always high. Thus, in a case where an ordinary pail and strainer was used, the count was 80,000. On the same day, from the same barn and cows, a sterilized pail and strainer being substituted, the count dropped to 5,000. All utensils must be strictly clean, and, if possible, steamed or sterilized. It was found that cleanliness depended both upon apparatus and proper methods of cleaning. 1. In every utensil all seams must be well soldered, to avoid hiding places for traces of dirt and coagulated milk. 2. Cold or lukewarm water must first be used, to avoid coagulation of particles of milk, then a cleansing with hot water, with soap or soda, and a final rinsing with hot water. After washing, cans or bottles should be turned bottom up on racks, and, if possible, steamed or sterilized. The following interesting experiment was made: Two samples were taken from the same can of milk—one from the top showing a count of 5,000, while the one from the bottom gave 80,000. As the can had been standing in ice, the lower part was cooler. The milk had also been strained, and creaming had not taken place, hence the conclusion was that the bottom of the can was not clean, and had contaminated the milk near at hand. On the whole, it was found that the simpler the pail the better; one that can be milked into quickly and cleaned easily is the best. The plain open pail gave the best results. It was found that metal strainers attached to pails were unsatisfactory, owing to difficulty in keeping them clean. Particles of dirt that might be removed later by straining are broken up by the force of the stream of milk and thus disseminated through the milk. Thus, samples of pails having strainers uniformly gave a higher bacterial count than when strainers were not used, other conditions being as nearly as possible the same. The best general strainers are absorbent cotton, cheesecloth, or Turkish toweling attached to the receiving cans by clothespins. If a metal strainer is then used, it should be as simple as possible, and the wire mesh must be carefully cleaned with a stiff brush. If an aerator or vats of any kind are used, they must be cleaned, and, when possible, steamed or sterilized. All joints and seams must be smooth, and the faucets and pipes likewise frequently steamed or sterilized. By requiring more apparatus to be kept clean, aeration, as ordinarily practised, increases the danger of bacterial contamination. The following experiment was made on July 22: It was found that samples of milk from pail and strainer on a certain farm averaged 3,000. After aeration by the farmer, according to his usual method, the samples gave a bacterial count of 1,404,000. Here, a man with clean cows, barns, and milkers was contaminating the milk by faulty utensils. In the hands of men

understanding the importance of strict cleanliness, the aerators are not a source of danger, but if the aerator is not strictly clean and in proper surroundings, the ordinary farmer may lose more than he gains by its use. Dirty ice, flies, floating dust, pipes, and faucets are sources of bacterial contamination. It has been found that with a clean barn, clean cow, and clean milker, the ordinary so-called "cow odor" is not present.

5. Process of Cooling.—This we have found to be one of the most important factors in the production of uncontaminated milk. The whole future condition of the milk depends a good deal upon its handling during the first forty-five minutes. The sooner it is brought to a temperature at or below 45° F., at which point the growth of bacteria is greatly inhibited, the better. Many inspections of premises that were clean enough to produce a clean milk gave disappointing results when the milk was allowed to stand for more than an hour without being cooled. Where the milk was brought below 45° F. within twenty or thirty minutes, a low bacterial count *always* resulted, other conditions being right. In an experiment made July 25, tests were made of milk collected from clean cows in a clean barn, the average count from the pail being 7,000. It was then cooled not lower than 60° F., by a slow process, and after two hours it was still standing at 60° F., when a bacterial count gave 89,000. Five days later, the milk, under apparently similar conditions, was cooled down to 45° F. within ten minutes from milking, and then showed a count of only 12,000. This experiment has been repeated at six different farms, in various localities, with similar results. We have found the temperature of springs during the summer to vary from 45° F. to 70° F., with an average of about 55° F. Hence, this method of cooling is uncertain and defective unless ice is added to the spring. Ice is always necessary to the farmer who is handling milk. When springs are used, the surroundings must be kept clean and the water uncontaminated at its source.

6. Transportation.—As soon as the milk is put into bottles or cans, it must at once be surrounded by ice. If they are kept standing in a vat, the temperature of the water must be, at least, 40° F., as the milk will then be a few degrees higher. This temperature must be maintained by ice, until the car is reached, if the milk is in bottles; if in cans, by means of jackets. The ordinary freight car should not be used. We have found that refrigerator cars, with doors at the end kept closed, are necessary. The cars should be loaded and unloaded from the center. The railroads can cooperate in this important work by supplying refrigerator cars and ice. When the dealer removes the milk from the car, it should be re-iced on the platform or at the depot and kept iced until delivered.

7. Much contamination can be avoided if the consumer would properly cleanse the bottles before returning them. They should be washed promptly, and never used for any other purpose. We have found cases where drugs, dirt, or even urine has been found in them. In houses with contagious diseases, no bottles should be returned but broken and thrown away. In apartment houses it is usually customary to collect the bottles in the basement where they are afterward sorted out by the dealers. All kinds of impurity thus get in, making it frequently impossible thoroughly to cleanse these bottles. Thousands of bottles every year are collected by Italians from the dumps and returned to the Bottle Association, which sorts them out, washes, and returns them to the owners.

In our inspection of creameries, it was found that thousands of Croton bugs were returned in bottles and boxes. The cans are also often returned with portions of decomposing milk remaining in them; the boxes containing the bottles may be mouldy, with parts of the wood rotten from being smeared with decomposing milk, and so forth. The railroads should be requested never to receive bottles, boxes, or cans containing any fluid milk. We found that boxes and cans are often thrown off from the train by the roadside, where they may be left for hours, exposed to the sun. Utensils subjected to this treatment are only fit to be used again after sterilization, and farmers usually have no such facilities; the creameries may have, but seldom use them.

The various data here recounted are the results of a summer study of the milk question. The information is the result of thirty visits made to various farms and dairies, some at a distance of 180 miles. Each of these visits consumed, at least, one day, and some several days, so that a thorough study of the matter could be made. In the work of the commission, the individual farm or dairy, and not the milk company, has been regarded as the unit for study and investigation. It was found necessary to work in this manner, in order to get good results; in some cases, several visits were made to a given plant. As an example, a large plant was visited on August 11; the farm was visited during milking time. The notes show that the cows were fairly clean, the barn was defective, showing hay protruding from the ceiling and covered with cobwebs and dirt. Windows dirty. The barn had a southern exposure, so that the sun increased the heat. The manure gutter was not clean; the bedding of shavings had not been removed. Various articles were stored in the barn, such as feed, farming utensils, and the clothing of the men. The cows were getting full rations of hay; the animals were hot and restless, and covered with flies, which necessitated a constant moving of the tail. No means were supplied for keeping the cow standing during milking. The milk was strained in the barn, and with a wire strainer, which was seen to be bent and rusty. The dairy-room was hot and sunny, showing dust and flies. The milk was passed over an aerator, in which the temperature of the water was found to be 60° F. The receiving vat and stationary vats were not covered, so that flies and dirt got in. The bottles were standing in ice-water at 50° F. A fair sample of milk produced under these conditions and tested at once showed a bacterial count of 455,000.

Suggestions as described in the paper above were offered, and four days later a second visit was made. As the result of specific directions in the barn the walls were whitewashed, windows cleaned, and green shades had been placed at the windows having a southern exposure. The floor was cleaned, and the bedding had been removed; the manure gutter was also clean, and land-plaster had been sprinkled on the floor and manure gutter. All storage of feed and utensils had been removed. The cows were getting scant grain rations so that there was not a large pile of hay before the animal that would fill the air with dust and induce movements of the body. The cows were well cleaned. The barn was cooler, and hence the animals were not so restless. The milk was not strained in the barn, but removed at once to the dairy. The dairy-room was clean, dark, and cool, with receiving and stationary vats covered with cheesecloth. The temperature of the water in the aerator was 40° F. The bottles were standing in ice-water at 38° F. A fair sample of milk thus produced showed a count of only 3,000 to the c.c. This is not an exceptional condition, as a similar experience was repeated at four different times and places. This shows that an

elaborate and expensive plant is not necessary to put out clean milk. What is needed is intelligent attention to detail. A small as well as a large producer can furnish clean milk. The following example will illustrate an experience with a small dealer, the visit being made September 5. Notes as follows: The cows, barn, and man were fairly clean. Utensils fair. No aerator and no steam. Ice was being used sparingly. Milk drawn under these conditions was placed in water at 70° F., then taken to the creamery for bottling and sent to the city. An examination here showed a count of 89,000. Various suggestions were offered, and the second visit made in eight days. Result—cows and barn well cleaned, the milk strained through absorbent cotton, and cheesecloth attached by clothespins to a forty-quart can which was kept standing in a box surrounded by ice. This can had previously been steamed for twenty minutes at the creamery. The can was then taken to the creamery and placed in a vat of ice-water, at a temperature of 40° F. In three hours the temperature of the milk stood at 44° F. It was then bottled and sent to the city. A sample of this milk showed a count of 5,400, as the result of the few simple changes suggested. Even a creamery is not necessary for a small dealer to put out milk up to the standard of the commission. As an example, milk was sent from a small farmer, where cooling to 40° F. was practised within fifteen minutes after milking. This milk was sent to the city in forty-quart cans, surrounded by jackets. Samples taken on the platform in New York at 3 A.M. showed a count of only 3,000.

All the visits made to these farms were educational. The whole family, including wife and children, became interested and co-operated in the work. The attention of neighbors was also attracted to the improvements, which were often imitated, and formed the subject of evening discussion at the village grocery store.

The commission has no special method to advise, but asks a hearty co-operation from every one concerned in handling the milk. The methods must vary with each plant. In general, it may be said that the following three heads include the essential conditions: First, strict cleanliness, which includes the barns, yards, cows, milkers, and all utensils. Bacteria which get into the milk by means of dirt are thus thoroughly excluded. Second, rapid and sufficient cooling of the milk. The few bacteria that do get in are thus prevented from growing. Third, thorough icing around the milk until it reaches the consumer. The production of toxins from the growth of bacteria is thus retarded.

In every case the dealer has been able to reach the standard of the commission without expensive apparatus, by following the indicated details. The one thing always necessary is plenty of ice. At the same time, great labor has been done by farmers and dairymen, as the result of suggestions by the commission. New plumbing has been put in, new dairy-rooms have been built, floors have been cemented, ceilings made tight, and time and endeavor have not been spared. One dealer was so impressed with the subject of right conditions, that a special new barn was put up in order to meet them. Two others are planning new barns that will insure hygienic conditions. Even where the milk has not reached the standard for certifying, great advances have been made, and the general output improved. Eight dealers are now putting out some of their milk up to the standard of the commission. They are as follows: Slawson Bros., Briar Cliff Farms, T. W. Decker & Sons, Mrs. Van Zandt, Sheffield Farms, Harlem (Mr. Tuthill), Century Co., Locust Farms, and Mr. Keller. Many others are making changes and applying for a certification, who will doubtless pass the test of the commission.

In spite of the summer having been the hottest in thirty-one years, all those who have been certified have kept up to the standard under most trying conditions. The thanks of the commission, and of the community at large, are due to these dealers who have shown great interest in this work, and have not spared labor or sacrifice in keeping up to the standard. The milk of each dealer has been examined about twice a month during the summer, and labels furnished that can be placed in the mouth of the bottle as a proof of certification. The bottle for examination is collected from the dealer in the morning, placed in a bag surrounded by ice, and at once taken to the laboratory. If the milk shows a test close to the limit established by the commission, a second examination is made in a few days. In the meantime, an effort is made to find out the source of the trouble, in order that it may be corrected.

The commission feels gratified at the interest excited in this movement on the part of the farmers, milk dealers, the daily press, and the dairy journals. It is hoped by this movement to inaugurate a general improvement in the production and handling of milk destined for large cities.

LABORATORY AID IN SURGICAL TECHNIQUE.*

By George B. Broad, M.D.,
Syracuse, N. Y.

Instructor in Pathology and Bacteriology, Syracuse University, College of Medicine; Gynecologist, Syracuse Free Dispensary; Assistant Gynecologist, St. Joseph's Hospital, Syracuse.

Wound infection is a matter of such grave moment that I feel I need no apology for presenting a few facts learned in the laboratory bearing upon this all-important subject.

It has occurred to every one engaged in surgical work to any extent to have now and then a case of suppuration, where apparently the utmost care was used in preparation and during the surgical procedure. Suppuration cannot occur without infection from some source, and to trace this source has been my endeavor.

My first work along this line dates back to 1897, when a series of experiments with hands known to be infected was undertaken. Prior to that time, rubber gloves had not been generally used, and the operator was sometimes compelled to work in virulent pus, both during the operation and at subsequent dressings. These hands by culture-testing were known to be infected by the staphylococcus pyogenes aureus. Then began a systematic effort to rid the hands of this infection. Strong antiseptics were used, and culture-tests made after their use, to note the effect of antiseptics on hands known to be infected.

First bichloride of mercury was used in strengths of 1-2000 and 1-4000, the hands being first scrubbed with green soap and water. The hands were soaked in bichloride of the above strengths for periods varying from five to fifteen minutes. In every instance after these washings, culture-testing always developed the staphylococcus.

After two weeks' work with bichloride, the infection still persisting, this was dropped and the permanganate-oxalic-acid method tried. This method was used for

*Read before the Syracuse Academy of Medicine, February 21, 1901.

two weeks, cultures being taken after the washings. Here, as with the bichloride method, finger scrapings and pieces of skin in culture media always developed the staphylococcus aureus.

Formalin was next used in strengths varying from 1 to 4 per cent. With it results were at first more gratifying. No growth would appear until about forty-eight hours, when the bouillon would begin slowly to cloud. But with the formalin, as with the other antiseptics, at no time did the growth of the micro-organism fail to appear. Then followed scrubbings with green soap and water, no antiseptics being used, but still the microbes developed. Then followed a rest of several weeks, our victim going out of town. On his return, culture-testings still proved that the staphylococcus pyogenes aureus was present, but guinea-pig inoculations showed it to be of lessened virulence. Disgusted with our findings, the subject refused further experiment.

Here was an infection which extended over a period of three months and persisted in spite of strong antiseptics. How much longer it remained I do not know. I think we have a right to say that the unprotected hands can be, and often are, a source of infection to our patients, even though washed in strong antiseptic solutions. The culture medium used was bouillon and agar-agar.

The possibility of silk being sometimes the cause of infection led to some work with it, to see just when it was rendered sterile by boiling. Different sizes of silk from one up to twenty were first infected with a pure culture of the staphylococcus pyogenes aureus. This organism was chosen because by far the larger number of cases of suppuration are due to its presence.

The silk was boiled up to seventy minutes, pieces being removed under aseptic precautions every five minutes. The water was brought to a boil before the silk was dropped in, temperature 212° F., without pressure. We found, as might be expected, the larger the silk, the longer the time required to render it sterile.

Number 20 silk was boiled sixty minutes before becoming sterile; No. 16, forty-five; No. 12, forty; No. 8, thirty-eight; No. 6, thirty-five; No. 4, thirty minutes, and all below No. 4 was boiled twenty-five minutes, except No. 1, in which no growth was obtained after eighteen minutes' boiling.

I admit this is a pretty hard test, for some silk may not be badly infected, and perhaps no silk would be as badly infected as was the silk used for these tests. Still, I know of no other ground on which to work, for we must assume that silk is infected unless we know otherwise, and must sterilize on this assumption.

Silkworm gut as a means of infection was next considered. The silkworm was used as it came from the factory. Work was done also with silkworm gut, which had been infected with the staphylococcus aureus. No growth could be obtained from either after forty-five minutes' boiling. We had previously, as routine, boiled our silkworm gut five or six hours for two or three consecutive days. This long boiling may be necessary with some silkworm to render it sterile, still I know of no pyogenic microorganisms that can withstand anything like that amount of boiling. Certainly, in an experimental way no growth could be obtained after silkworm had been boiled for the time above stated. I am strongly inclined to believe that much of the infection laid at the door of silkworm gut is really an infection from the skin of the patient, or may even be a post-operative infection.

The sterilization of catgut is a question of extreme importance. During 1896 and 1897 most of the catgut with which we worked was prepared by the bichloride method. The gut, after the fat had been dissolved out, was put in a 1-100 alcoholic solution of bichloride and preserved in alcohol or glycerin alcohol. This method was a fairly good one, and it was exceptional that any infection was found on culture-testing.

Formalin was next used in catgut preparation in strengths varying from 2 to 8 per cent., following somewhat closely the method of Vollmer and Kossman, who made strong claims for this method. With me it was not satisfactory. I found I could sterilize the smaller gut, as numbers 0, 1 and 2, but anything larger than No. 2 was uncertain.

I have had some experience with the ammonium-sulphate method as described by Elsberg. This method is based on the chemical fact that animal tissue can be boiled in a solution of ammonium sulphate without disintegrating, which fact is true. The catgut would not disintegrate, but its strength with me was much impaired. It could, of course, be rendered perfectly sterile by boiling. The method which seems to me the most perfect is the sterilization of catgut by dry heat. The gut, after the fat is dissolved, is placed in parchment or bond envelopes, doubly sealed. These envelopes when sealed are subjected to a heat of 300° F., or practically 150° C., for three hours, and on the following day to the same heat for one hour, to kill any spore which may have resisted.

Culture-tests have shown that catgut prepared in this way is absolutely sterile. When this heat is maintained in a proper oven, asbestos-lined, to prevent strong radiation, we have a gut which is strong, sterile, and in every way desirable. These facts are borne out by clinical experience. It has been used by Dr. A. B. Miller of Syracuse as well as myself for the past two years in both hospital and private practice without a single case of suppuration in the line of suture from its use. It seems to me in this method we approach nearest the ideal, for we can produce a gut strong and absolutely sterile by the simplest and best of all agents, viz., heat, without the use of a single chemical. It is also convenient and can be carried in the surgeon's grip without fear of contamination.

Rubber gloves and their sterilization were next undertaken. Rubber gloves were first infected with the staphylococcus aureus. These gloves were boiled and portions of them removed under strict asepsis, at intervals of five minutes up to thirty minutes. Rubber boiled fifteen minutes gave a growth, while rubber boiled eighteen minutes was sterile.

One other source of infection which may or may not be of much practical importance is the expired air. A few limited experiments have convinced me that bacteria are given out from mouth and nose. Whether these bacteria are given out during respiration or during speech is a matter of little moment to the surgeon. A crude mask was devised and worn for one hour, at the end of which time pieces of gauze through which the wearer had been compelled to breathe were removed. This gauze was contained in a little chamber held from the face so that any contamination from perspiration could be excluded. Examination of this gauze has always given a growth.

The bacterial growth from this gauze was made up largely of staphylococci, diplococci, and an occasional bacillus. My work along the line of expired air is so limited that it can count for but little as yet. Still, in this way we may be able to explain an occasional case of suppuration, when an assistant or observer has been present who was suffering at the time from some suppurative disease of the nose or mouth.

72 Cortland Avenue.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., 51 Fifth Avenue.

New York, October 19, 1901.

THE OFFICIAL REPORT OF THE CASE OF PRESIDENT McKINLEY.

THE official report of the case of President McKinley, containing, as it does, detailed accounts of the operation, treatment, and autopsical findings, will be read with becoming interest by all who have so eagerly awaited the final expressions of opinion of the gentlemen in attendance. Much of what appears has already been anticipated by the full reports which came from time to time from the sick-room, either in the shape of bulletins and personal statements, and which were so widely published by the medical and secular press. Still, it is now a matter of history to print the story in its present connected and authoritative form As a description of a now famous case, it lacks nothing in completeness of detail, accuracy of statement, or frankness of opinion. As such it will stand on its merits as a notable contribution to medical literature.

While, doubtless, the account will be read from beginning to end with varying interest in the points discussed, it is safe to say that the elaborate and carefully prepared autopsical report will receive the greatest attention. There have been very many different opinions expressed among medical men generally as to the real cause of death, and it will be with great satisfaction that the accurately described details of the post-mortem examination can be studied with becoming thoroughness.

All discussion has, of course, centered on the cause of the gangrene in the bullet track. The suspicion that it might have been due to a poisoned ball was very quickly and properly dispelled. In fact, we now have bacteriological proof that the wound was not at all infected primarily, but that a necrotic process developed later, and steadily progressed until the end. It cannot be positively demonstrated that the lesion of the pancreas had anything directly to do with the induction or continuance of this tissue change.

Doubtless, the theory that gangrene was induced by a lack of vital resistance in tissues involved will appeal to the greater number as being the most reasonable one. There were certainly many contributory causes to such an end. The patient was of sedentary habits, given to obesity, had a feeble heart action, and was aged beyond his years, with the usually deficient oxidation of his tissues.

We know that whenever a bullet passes through the living body it leaves a track of contusion, more or less well marked, according to the size or velocity of the projectile and the nature of the tissue which it traverses. If the patient survives the immediate injury, and recovery is a physiological possibility, the contused tissue undergoes one of two processes: If the bruise is not too severe and the patient's circulation is active, the tissue recovers. If not, it undergoes putrefaction or necrobiosis. Naturally, what in one patient with a good heart action and active vital processes would be a practically harmless contusion, in another with a weak and thin-walled organ would be exactly the opposite.

It is therefore not unreasonable to suppose that the necrosis tissue in the case of the President represented originally the contused tissue into which the enfeebled heart was unable to force the blood current so as to overcome the stagnation. This condition of affairs, associated with the feeble heart, again would explain the rapid pulse which was such a marked and ominous feature of the case, and which so sadly and effectually set at naught the optimistic predictions of some of the medical attendants.

THE MILK SUPPLY OF LARGE CITIES.

ONE might think, from the outcry raised on all sides by Koch's qualified pronouncement with regard to the communicability of bovine tuberculosis to the human subject, that consumption is the sole disease which can be transmitted by milk, and not, as is really the case, that various maladies are originated and spread by this means.

How many epidemics of typhoid fever, scarlet fever, and diphtheria, which have played sad havoc among communities, have been clearly traced to an impure milk supply? The commotion excited by the recrudescence of the theory brought forward by the German savant, at the British Congress on Tuberculosis, has unduly overshadowed this phase of the question, and the general public, unless instructed to the contrary, will be apt to imagine that the dangers arising from unclean milk have been grossly overestimated by the medical profession. The fact may be here plainly stated that milk in infected condition is possibly one of the most fertile causes of disease in a crowded population, and a standing menace to the health of the inhabitants of large cities.

It will be well for laymen to ponder over, and to grasp thoroughly, the truth of this proposition, and to bestir themselves in an effort to secure a milk supply as pure as possible.

On Monday, September 23, the Medical Society of the County of New York met at the Academy of Medicine, and heard a report from the Milk Commission appointed in January, 1900. Dr. Henry Dwight Chapin, one of the commissioners, whose communication appears in this issue, says that heretofore most of the work of milk commissioners has been taken up with the chemical problems; but, from a chemical point of view, they had found the milk good. The standard prescribed by the commission is that the acidity must not be higher than 3 per cent., and that the milk must not contain more than 30,000 bacteria of any kind per cubic centimeter. "The amount of bacteria in the milk used

in the city of New York is something alarming. Out of twenty samples, examined on a winter's day, November 19, the lowest contained 90,000 germs, and the highest 2,280,000, while on June 29, the thermometer standing at 90 degrees out of twenty samples examined, the lowest contained 240,000, and the highest 516,000,000 per cubic centimeter."

Dr. William Hallock Park of New York had, in the *Journal of Hygiene* for July, an article on the same subject. He pointed out that nearly all the New York milk is transported to the city by railroads, most of it traveling a distance of 50 to 350 miles. The milk is delivered in the city about 2 A.M.; consequently, when it is shipped at a point distant 350 miles from New York, it must start on its journey as early as 8 A.M. on the previous day. Under existing conditions, most of the milk which reaches New York must, therefore, have been kept from twelve to thirty-six hours. Twelve hours more must elapse before the last of the milk is delivered. The problem, then, in New York, and in other cities of great size, is to furnish milk in a condition suitable for food, after it has been kept from twenty-four to twenty-eight hours.

The number of bacteria present in the milk of healthy cows depends, says Dr. Park, almost entirely on four things: (1) The original amount of germicidal substance in the milk. (2) The amount of bacterial contamination on or after milking. (3) The length of time which has elapsed since milking. (4) The temperature at which the milk has been kept.

Reviewing these postulates in detail, the measures to bring them into effect would seem to call for the following precautions: In the first instance, to insure as far as is feasible a supply of healthy animals. Next, to enforce stringent regulations as to the cleanliness, ventilation, and drainage of the sheds in which the animals are kept, the cleanliness of the persons employed in milking, and especially that scrupulous attention be paid to the thorough cleansing of the utensils used. Then it is essential that transportation of milk to the large centers of population should be much more rapid than now, and lastly, that the milk be subjected to a rapid and sufficient cooling process. If all these requirements could be fulfilled, there can be no doubt that a satisfactory milk supply would be the sequence. Of course, perfection cannot be hoped for, but much may be done by the enforcement of the rules sketched above.

Farmers should be compelled to house their beasts in sanitary buildings, to insist that their employees practise strict cleanliness in all the details of milking, and that dairy owners within a radius of one hundred miles from a city should be forced to send their afternoon milk on the train of that evening, and those farther off to send the morning's milk on the morning's train. The poor are far greater sufferers from the contaminated milk than the well-to-do, and the great mortality among the infants of the tenement districts in all large cities is principally due to this cause. The milk supply of New York City will bear comparison with that of any city of the world, but nevertheless, even here there is room for much improvement. It may, however, be anticipated that the labors of the Milk Commission will result in the providing of rich and poor alike with milk comparatively free from the germs of disease.

VIRCHOW.

On October 13 Virchow attained his eightieth birthday, sound in mind and body, earnest in purpose as of old, and honored with congratulations from the entire scientific world of medicine.

Seldom is it allotted to man in any sphere of high human endeavor to round out so triumphantly a career in which honor, fame, and distinguished worth vie with each other in proclaiming him a leader of his kind.

In his chosen branch of medical research he stands the pre-eminent master. His work on Cellular Pathology from the time of its first publication in 1858 until the present has been a leading textbook for every student of pathology.

Laying the foundation for the present accepted doctrines of the study of diseased processes, it has held its own along with all other advanced works on the healing art. Methods of investigation which have been elaborated since that time have simply fallen in line with the broad, comprehensive, and all-pervasive doctrines of the great teacher. Without such an impetus, humoral and tissue pathology would still hold sway and the real progress of to-day would have been impossible.

Even bacteriology, which appeared at first to militate against the theory of fundamental cell changes, now adds its testimony to the stability of Virchow's original views. Instead of causing disease as such, the various pathogenic germs merely provoke those cellular changes which in themselves constitute the true essence of all morbific changes. Thus Virchow's work not only placed the study of pathology on an entirely new basis, but has maintained it there for nearly half a century.

Not only in medicine has he won deserved distinction, but his researches in anthropology and archæology have made him an authority in each of these branches. Then, too, as if a busy life should not be made even more so, he adds to his other high qualifications those of a statesman, philanthropist, and sanitary reformer; and with a conscious power of right he has made his influence felt in every one of the varied directions in which it has been exerted. But his tasks were commenced early and long continued, and the harvest of his work is such as almost to bewilder us with its richness.

No wonder that scientific men everywhere hasten to do him honor and are thankful that he is still spared to them as the exponent of those higher principles and loftier motives which benefit humanity, broaden science, mitigate suffering, and heal the sick. Congratulations, then, to the Grand Old Master, and may his declining years be full of light and peace!

THE SEMI-ANNUAL MEETING OF THE STATE SOCIETY.

The experiment of holding a strictly and exclusively scientific meeting of the Medical Society of the State of New York in this city has been to all intents and purposes a very successful one. The business committee worked long and hard to secure good papers from representative men, and its efforts have been rewarded in a way that can leave no doubt as to the utility of a precedent now so auspiciously established. The results of the new plan also prove that enough of good material can be obtained from

the active members to occupy the attention of two semi-yearly sessions of the society. The large attendance of practitioners from distant and widely scattered districts of the State gives a practical endorsement to the movement, and is the strongest possible argument for its utility and continuance.

It is fair to say that the moral effect of such a measure will have a wide influence for good in instilling a more diffusive element of working force among the membership than can be attained by the hampering and distinctly local influences of Albany meetings.

From a purely scientific point of view it is a question which is the mountain and which is Mahomet. A half-yearly meeting in a great cosmopolitan center is at once a stimulus and an inspiration, giving breadth of view and directness of purpose which is next to impossible of attainment in a provincial town.

It is quite true that for purely legislative purposes there is an advantage in assembling once yearly in the Capital, but outside of such consideration there is no reason why not only Greater New York but other large cities throughout the State should not be visited in turn for purely scientific work. Then also the social element of these meetings is by no means an unimportant consideration with medical visitors, giving them opportunities for the formation of pleasant and profitable acquaintances with those leading men in different localities whose busy and exacting duties do not permit them to take long journeys for the mere gratification of reading a condensed and time-limited paper. All of these varied conditions properly fulfilled made the meeting in New York a markedly successful one.

INTERNATIONAL CONFERENCE OF AMERICAN STATES.

At the coming International Conference of American States, to be held in the City of Mexico, a plan, devised by Surgeon-General Wyman of the Marine Hospital Service, for the uniform sanitation of all North and South American ports, is to be submitted.

It is plain to see that an international agreement to this effect would be of the greatest importance to commerce and to public health, and would place the entire quarantine system of this continent on a reasonably consistent and firm footing.

The delegates from the United States, who for obvious reasons are intensely interested in the question, will formally present it to the Congress and urge the adoption of the necessary measures of uniformity of action.

Mexico, Central America, and South America will thus be asked to act in the matter of preventing the spread of infectious disease by a distinct international agreement of the health authorities of the respective countries.

The general plan provides for the sanitary improvement of harbors, sewerage and drainage, and the elimination of infection from buildings.

Some special preventive measures are to be instituted against the spread of yellow fever. In the latter respect, the American delegation will have much to suggest in the way of quarantine reforms which past experiences, especially during the late Spanish war, have made so instructive, so valuable, and so practical.

The general principles upon which yellow-fever quarantine are based are now so well understood that there will be little difficulty in arriving at some general understanding for a comprehensive working-plan.

The suggestion of Surgeon-General Wyman is to the effect that an international sanitary commission be appointed, consisting of five members, two of which shall be residents or citizens of the same republic, "one shall be learned in the law, one shall be a physician and sanitarian, one shall be a sanitary engineer, and one shall be a commercial representative." Thus, it will be seen that all the different State, commercial, and sanitary interests are to be duly considered in forming a consistent, impartial, and powerful board of control. This is as it should be, for it gives the best possible basis for the proper working of a comprehensive and beneficent scheme of protection against any and every form of contagious disease. There is certainly every argument in favor of adopting the plan proposed. Quarantine of this kind is useless unless it can be general.

News of the Week.

New Hospitals in New York City.—The State Board of Charities has approved of the incorporation of the following institutions in this city: The Jewish Hospital of Booklyn, to erect, establish, and maintain a hospital which shall afford medical and surgical aid to sick or disabled persons, without regard to their creed or nationality; the Cosmopolitan Hospital Society of New York City, to establish a hospital wherein the method of treating the sick shall be according to the Eclectic school or theory; the Deachonian Dispensary, to maintain in New York City a dispensary wherein poor persons, without regard to race, nationality, religion, or sex, may receive free medical treatment and attendance according to the Eclectic school or system of medicine.

The Health of the Army.—In his annual report to the Secretary of War, Surgeon-General Sternberg notes that the health of the army has been unusually good during the calendar year 1900. The admission rate to hospital for all causes, with a mean strength of 100,389 in 1900, was 2,311.81 per thousand of strength as compared with 2,178.06 in the previous year; but during the year 1899 only 39,280 men, out of a total of 105,546, were serving in the Philippines, while during the last year 66,882, of a total of 100,389, were thus serving. In the Philippine Islands, with a mean strength of 66,882, the admission rate was 2,621.96 as compared with 2,395.52 in the previous year, this increase being mainly due to disease among the volunteers, the ratio for which rose from 1,859.21 to 2,761.79. The regulars, on the other hand, showed a marked decrease in the ratio of admission for disease, which fell from 2,454.1 to 2,197.763. Two-thirds of the admissions for disease were caused by malarial fevers and diarrhœal diseases. The deaths from all causes amounted to 28.75 per thousand of strength as compared with 30.68 in the previous year. Disease occasioned 20.26 deaths, the principal cause of the fatalities being dysentery, which, with other intestinal diseases, gave a rate of 9.08. The rate from injury amounted to 8.49. The death rate in China was large, 47.76 per thousand of strength; 23.62 from disease, and 24.14 from injury. The health of the troops in Cuba during the year was excellent. As a result of American occupation, nearly

every city and town has had its sanitary conditions improved.

The Establishment of Psychophysiological Laboratories.—The Fifth International Congress of Criminal Anthropology, in its meeting at Amsterdam, September 9–14, 1901, passed a resolution in favor of the establishment of a psychophysical laboratory for the practical application of physiological psychology to sociological and abnormal or pathological data, especially as found in institutions for the criminal, pauper and defective classes, and in hospitals, and also as observed in schools and other institutions.

Dinner in Virchow's Honor.—About one hundred and twenty-five friends, pupils and admirers of Dr. Rudolph Virchow, the eminent German pathologist, assembled October 12 at Sherry's to celebrate, with a dinner, the eightieth birthday of Dr. Virchow. In observing the day in this manner the medical men of this city acted in common with the profession in many of the great cities of the world.

Dr. William Osler presided. The toast, "Dr. Virchow as a Pathologist," was responded to by Dr. William H. Welch of Johns Hopkins University. Dr. A. Jacobi spoke on the subject, "Dr. Virchow as a Citizen," and Dr. Andrew H. Smith gave "Personal Reminiscences of Dr. Virchow."

Among those present were: Dr. Frederick Shattuck, Dr. William H. Welch, Dr. A. Jacobi, Professors Dercum and Wilson of the University of Pennsylvania, Dr. J. D. Bryant, Dr. Andrew H. Smith, Dr. C. L. Dana, Dr. George F. Shrady, Dr. William Osler, Dr. John A. Wyeth, Professor William H. Thomson, Dr. Theobald Smith, Dr. Leonard Webber, Professor Bernard Sachs, Dr. E. G. Janeway, Professor Roche, Professor Henry Hunn, Dr. Carmalt, Dr. W. P. Northrop, Dr. Paul Munde, Dr. J. H. Musser, and Dr. Sayre.

At the celebration of Professor Virchow's birthday at the Pathological Institute, Berlin, on the same date, the Secretary of State, the Secretary for Foreign Affairs, the Prussian Ministers, the entire faculty of the College of Medicine of Berlin, and deputations from all the universities were present. Professor Virchow had an enthusiastic reception, and he held the attention of the audience for nearly two hours while he reviewed the progress and development of pathological science.

Medical Society of the Missouri Valley.—The fourteenth annual session of this society convened in St. Joseph on Thursday, September 19, President Treynor in the chair. After passing resolutions on the death of the President, the society adjourned to allow its members to attend the McKinley memorial services. On Thursday evening the society boarded a special train of Pullman sleepers for Eureka Springs, Ark., where the annual outing occurred, and the regular program carried over from St. Joseph was presented. On Friday evening a reception and ball were tendered the visitors by the local profession and citizens of Eureka Springs, and Saturday was devoted to sight-seeing in the mountains, several tallyho coaches and sixty saddle horses being provided for the purpose. After a sumptuous dinner on Saturday evening the members left for the return trip arriving in St. Joseph on Sunday morning. Following is a list of officers elected for the year: *President*, R. E. Moore, Omaha; *First Vice-President*, A. D. Wilkinson, Lincoln; *Second Vice-President*, M. F. Weymann, St. Joseph; *Treasurer*, Donald Macrae, Council Bluffs; *Secretary*, Charles Wood Fassett, St. Joseph. The semi-annual meeting will be held in Lincoln in March, 1902.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the Medical Corps of the Navy, week ending October 12, 1901: October 4—Surgeon L. L. Von Wedekind, detached from the Puget Sound Naval Station and ordered home and to wait orders. Surgeon O. D. Norton, detached from the *Monadnock*, on reporting of relief, and ordered home and to wait orders. P. A. Surgeon D. H. Morgan, ordered to the *Philadelphia*. P. A. Surgeon A. W. Dunbar, detached from the Naval Hospital, Mare Island, Cal., and ordered to the Puget Sound Naval Station. P. A. Surgeon S. G. Evans, detached from the *Solace*, upon reporting of relief, and ordered home and to wait orders. P. A. Surgeon A. R. Alfred, detached from the Marine Barracks, Cavite, P. I., and ordered to the *Monadnock*. P. A. Surgeon J. M. Moore, detached from the *Franklin*, upon reporting of relief, and ordered to the *Indiana*. Assistant Surgeon C. G. Smith, detached from the *Alvarado* and ordered to the *Marietta*. Assistant Surgeon F. E. McCullough, detached from the *Philadelphia* and ordered to the Naval Hospital, Mare Island, Cal. Assistant Surgeon J. F. Murphy, detached from the *Indiana*, upon reporting of relief, and ordered to the *Solace* for temporary duty, and then to the Marine Barracks, Cavite Naval Station. Assistant Surgeon W. H. Bell, ordered to the *Franklin*. Assistant Surgeon D. N. Bebee, detached from the *Marietta*, upon reporting of relief, and ordered home and to wait orders. Assistant Surgeons A. M. Fauntleroy and L. W. Bishop, commissioned assistant surgeons from September 28, 1901. October 7—Surgeon C. F. Stokes, detached from the *Oregon* and ordered to the *Solace*. Surgeon G. A. Lung, detached from the Marine Barracks, Cavite Naval Station, on reporting of relief, and ordered home and to wait orders. Surgeon L. W. Spratling, commissioned surgeon from September 28, 1901; detached from the Naval Hospital, Cavite, P. I., on reporting of relief, and ordered home and to wait orders. P. A. Surgeon M. S. Guest, detached from the Naval Hospital, Philadelphia, Pa., and ordered to the *Solace*, October 17, for temporary duty, and ordered to the Cavite Naval Station, on arrival on the Asiatic Station. P. A. Surgeon A. Farenholt, ordered to the *Independence*. P. A. Surgeon M. K. Johnson, detached from duty at Guam, on reporting of relief, and ordered to the Marine Barracks, Cavite Naval Station. Assistant Surgeon C. D. Langhorne, ordered to the Naval Hospital, Naval Home, Philadelphia, Pa. Assistant Surgeon W. Seaman, detached from the *Independence*, on reporting of relief, and ordered to the *Solace* for temporary duty, and ordered to duty at Guam, on arrival at that place. Assistant Surgeon H. M. Tolfree, detached from the *Columbia* and ordered to the *Solace* for temporary duty, and ordered to duty at Guam, on arrival at that place. October 8—Assistant Surgeon J. B. Dennis, detached from the Naval Academy and ordered to the Naval Hospital, New York. Assistant Surgeon R. M. Young, detached from the New York Navy Yard and ordered to the *Columbia*. Assistant Surgeon R. M. Fauntleroy, ordered to the Navy Academy. October 9—Assistant Surgeon J. J. Snyder, detached from duty at Poloc, P. I., and ordered to the Naval Hospital Cavite, P. I., for treatment. P. A. Surgeon J. A. Guthrie, detached from the *New York* and ordered to duty at Port Isabella, P. I. Assistant Surgeon R. K. McClanahan, detached from duty at Port Isabella, P. I., and ordered to duty at Poloc, P. I. Assistant Surgeon F. A. Asserson, detached from the *General Alava* and ordered to the *New York*. Assistant Surgeon F. L. Benton, detached from the *Brooklyn* and ordered home.

Demonstrator of Anatomy at the University of Pennsylvania.—Dr. Edward D. Holmes, for nineteen years connected with the medical department of the University of Pennsylvania as Instructor and Demonstrator of Anatomy, has resigned. He has been succeeded by Dr. Elijah Gregory.

A Health Board in Need of Money.—At a meeting of the Board of Health of Paterson, N. J., last week, it was stated that the board was in financial straits, and that there would probably not be enough money to carry it through the remaining six months of the fiscal year. The board decided to drop two auxiliary inspectors, giving the health office authority to employ them when urgently needed. One of these is a sanitary inspector of tenement houses, which need more attention in the winter than in the summer time.

Mrs. Huntington's Gift to Charity.—The mansion said to be the finest type in America of the Italian villa architecture, is to be given by the widow to some charity, probably a hospital.

Collection of Cigar Butts Forbidden.—Dr. John D. McGill of the Jersey City Board of Health has forbidden the collection of cigar and cigarette butts in the streets, and says that a health ordinance will be passed prohibiting traffic in these disgusting objects. The butts, with little preliminary cleansing, are chopped up and made over into cheap cigarettes.

Fire in a Hospital.—Fire was discovered one afternoon last week in the Paterson (N. J.) General Hospital. It was caused by defective insulation of an electric wire, and was extinguished before much damage was done. The ninety-five patients in the institution were all removed promptly, many of them being carried in blankets down the fire-escapes, by the nurses and orderlies, and were made comfortable in improvised beds on the lawn until the fire was put out.

Dr. Julius Galvani, Professor of Surgery in the University of Athens, died recently of heart disease. He was born in Zante in 1838, his father being an Italian, his mother a Greek. He studied medicine in Paris, and then returned to practise in his native town. Later, he moved to Athens, where he became chief of the surgical division of the Evangelismus Hospital. He was made professor in the university, but resigned at the end of a year for political reasons. Upon the death of Professor Aretæus, in 1893, he again took the chair of surgery and held it until his death.

A Latin-American League against Tuberculosis.—At the Latin-American Medical Congress, held in Santiago de Chile in January of the current year, a resolution was adopted providing for the establishment of an international commission for the prophylaxis of tuberculosis. This commission, charged with the duty of directing the combat against tuberculosis in the countries of Latin America, has for its President Dr. Emilio R. Coni of Argentina, and its Secretary, Dr. Lucio Córdova of Chile; its membership is made up of one representative from each of the countries of South and Central America, Mexico, and Cuba. Each member of the commission is charged with the organization of an autonomous league against tuberculosis in his own country, which is to send each year to the President and Secretary a brief report of the work it has accomplished. Among the objects which it is suggested that each league shall endeavor to secure are: Better homes for the poor, regulation of the hours of labor, the establishment of savings banks, a propaganda against alcoholism, obligatory instruction in hygiene in the public schools, declaration to the health authorities of all cases of tuberculosis, disinfection from time to time of every apartment occupied by a subject of pulmonary tuberculosis and always of one in which a death from this disease has occurred, isolation of the tuberculous in special hospitals or wards, the establishment of sanatoria, the organization of dispensaries for the treatment of respiratory diseases, the repression of bovine tuberculosis, and the sanitary supervision of all dairies and other places where milch cows are kept.

Typhoid Fever is prevailing extensively in St. Petersburg, one-fourth of all the patients in the public hospitals being sufferers from that disease.

Medical Strike in a Venice Hospital.—An account of a strike in the Civil Hospital in Venice is given in a recent issue of the *Pall Mall Gazette*. According to this story, the junior medical staff, twenty-seven in number, on September 23, sent an "ultimatum" to the Governors demanding a complete reorganization of the sanitary conditions of the hospital, an increase of their own salary, and an augmentation of their numbers. Failing a satisfactory reply by October 1, they threatened to strike in a body. The Governors, supported by the municipal and Government authorities, besides refusing any concession, have determined to replace all the signatories, who are at the same time held criminally responsible for leaving their posts before their successors are appointed.

A New York Health Commissioner Organizes a Medical Company.—Dr. William T. Jenkins of the New York City Board of Health has been in England for the past two months soliciting business for his medical company, a concern called the "Merchant Marine Hospital Service." In an interview in one of the English journals, he says he has made contracts with the owners of nearly a thousand British ships whereby he agrees to give all needed medical and surgical treatment to the crew during the stay of the vessel in any of thirteen designated ports on the Atlantic and Gulf coasts of the United States. The services of himself and his associates in this work he values at the rate of $15 for each ship, irrespective, apparently, of the number of the crew or the length of stay in port.

Medical Inspection of Schools in Orange.—Dr. D. Warren Poor has been appointed by the Orange (N. J.) Board of Education medical inspector of the public schools of the city. He is to visit each school daily and examine any pupil suspected by a teacher of having a contagious or infectious disease, and should the suspicion be well founded, the child will be sent home with a note advising that the family physician be called.

Alcoholism in the Army.—In his annual report to the Secretary of War, Surgeon-General Sternberg says that "the steady decrease of late years in the admissions for alcoholism among the men of the regular army is a matter for congratulation. Military officers may be said to be unanimous in their opinion that this was mainly the result of the establishment of the post-exchange or canteen at military posts. There is less drunkenness among troops in active service than in a command doing garrison duty in the times of peace."

College of Physicians of Philadelphia. Section on General Medicine.—At a stated meeting held October 14, Dr. J. A. Scott reported "a case of aneurysm of the aorta which ruptured into the pericardium" and showed the specimen. The patient had been a negro, twenty-eight years old, with a history of hard work, but with none of syphilis. There had on at least two occasions been hemorrhage in ad-

dition to the final fatal one, in conjunction with which tonic spasm occurred. On post-mortem examination the aneurism was found to be situated in the aorta just above, and practically involving, the sinus of Valsalva. Dr. Joseph Sailer read a paper entitled "A Case of Malignant Endocarditis and Brain Abscess with Unilateral Abscess." The case was an obscure one, but lumbar puncture and examination of the blood during life, as well as of the cerebral abscess after death, disclosed the presence of a microorganism corresponding to the staphylococcus pyogenes aureus. A discussion took place as to what constituted Kernig's sign, the consensus of opinion being that it consisted in inability to extend the leg on the thigh beyond an angle of 90° or 120° when the thigh was already flexed on the abdomen at an angle of 90°, with the patient in either the sitting or the recumbent posture. The phenomenon was further thought to be dependent upon some peculiar form of cortical irritation. Dr. Alfred Stengel presented a communication on "Iodic Purpura," reporting a case presenting this manifestation following the administration of five grains of potassium iodid thrice daily for the relief of asthma. In this as well as in other cases in which symptoms of iodism were present, elevation of temperature was also observed. A discussion on "Methods of Keeping Case Records in Private Practice" was participated in by Drs. F. A. Packard, J. P. Crozer Griffith, Alfred Stengel, J. K. Mitchell, Judson Daland, J. Alison Scott, and John H. Musser.

Victuals and Vices.—At a Purity Congress held last week in Chicago, a medical delegate read a paper on diet. He held that much of the sensuality in the world was due to the use of animal food, and looked on the products of the vegetable kingdom as active agents of sexual morality. "The cook," he said, "often leads to more drunkenness and excess than the saloonkeeper. High seasoning and rich animal foods lead to indigestion and ill-health. Ill-health weakens the will and breaks down the moral character. Total depravity is often nothing but total indigestion."

A German Professor on Weak Woman.—Professor Möbius of the University of Leipsic has just published a work which is regarded as a defense of the German professors in their opposition to women students. He says that women are physiologically feeble-minded, being a little brighter than boys, but far less so than men. He says no woman has ever advanced the intellectual life of mankind and regards them as incapable of so doing. Their intelligence is receptive, he holds, rather than creative, imitative rather than original, and, even in their own special branches, such as cooking, sewing, and teaching, the discoverers of new methods are always men. He deplores the extension to women of the benefits of higher education, the results of which, he says, are barrenness and invalidism.

Pathological Society of Philadelphia.—At a stated meeting held October 15, the President, Dr. H. A. Packard, delivered his annual address. Dr. Chas. W. Barr was elected President for the ensuing year, Dr. J. Dutton Steele, Secretary; Dr. Thompson Westcott, Treasurer, and Dr. David Riesman, Recorder.

Politics and Spectacles. Under the new franchise law in Maryland those who cannot read will be deprived of the ballot. In a study of their probable loss or gain through the workings of this law, the politicians have made the discovery that hundreds of voters of the poorer classes can read sufficiently well to ballot, but their sight is so defective that in the dimly lighted booths they will be unable to decipher the long lists of candidates on the ballot.

Accordingly, the managers of both parties have ordered many gross of spectacles of various magnifying powers, and they will have men at the different polling places to adjust the glasses to the eyes of the myopic or presbyopic voters.

Philadelphia Pediatric Society.—At a stated meeting held October 8, Dr. Alfred Hand, Jr., presented a paper entitled "A Cretinoid Child of Three Years." The patient was undersized and rachitic, deficient mentally, with a somewhat idiotic appearance and undue deposition of subcutaneous fat. The thyroid gland appeared deficient. Improvement followed administration of thyroid extract. Dr. J. H. McKee read a paper entitled "The Training of the Senses."

Bequests to Hospitals.—By the will of Thomas Elkinton, recently deceased, the sum of $5,000 is bequeathed, after the death of a widow and a sister, to the Jefferson Hospital, the Orthopedic Hospital, the Polyclinic Hospital, the University Hospital, and the Pennsylvania Hospital, each, the income from which is to be used in providing apparatus for deserving art-patients.

Advisory Board for the Pathological Institute of the State Hospitals.—The plan of reorganization of the Pathological Institute of the New York State Hospitals for the Insane undertaken by the State Commission in Lunacy is gradually taking shape.

In order to add to its efficiency, a great deal of careful thought was given to the matter of the appointment of an Advisory Board, whose duty it should be to aid in the development of the Institute, and the carrying on of its work on broad lines, and to assist the new Director soon to be appointed by its valuable advice. It is the aim of the reorganized Institute to carry on work in the sciences correlated with psychiatry much according to the original scheme, but with a few modifications calculated to meet more immediately the needs of the hospitals as expressed by the superintendents, and to meet some of the criticisms of the former plan. Original research in the various sciences having a bearing upon the subject of insanity will go on as before, but in addition thereto the Institute will be utilized to give special instruction in clinical psychiatry as well as methods of scientific research to the physicians on the staffs of the hospitals for the insane, and to young men about to take up an asylum career. In order to obtain this clinical experience, the institution needs to be combined with a hospital for the insane, and to bring this about it is for the present to be connected with one of the asylum's on Ward's Island, and until such time as a reception hospital for the insane can be established in Manhattan.

In selecting the members of the Advisory Board, the Lunacy Commission deemed it expedient to have the three University Medical Schools of New York City represented, viz. Columbia, Cornell, and Bellevue University. Furthermore, it was considered to accord to the chief sciences correlated with psychiatry representation upon the Advisory Board. These sciences are pathology, chemistry, psychology, and general biology. Inasmuch as the Pathological Institute was created for the utilization of the material of all the State Hospitals, and for the purpose of raising the standard of scientific study, treatment, and care of the insane under State care, it was thought best that these institutions should also have a voice upon the Advisory Board. A member to represent general clinical medicine and neurology was likewise selected.

Accordingly, the Commission in Lunacy has established an Advisory Board consisting of the following gentlemen: J. McKeen Cattell, Professor

of Psychology, Columbia University, James Ewing, Professor of Pathology, Medical Department of Cornell University; Christian A. Herter, Professor of Pathological Chemistry, Bellevue and University Medical College; Hermon C. Bumpus, Assistant to the President of the American Museum of Natural History, to represent the department of general biology; Henry Hun, Professor of the Diseases of the Nervous System, Albany Medical College, to represent neurology and general clinical medicine; Dr. Charles W. Pilgrim, Superintendent of the Hudson River State Hospital at Poughkeepsie, and Dr. A. E. Macdonald, Superintendent of the Manhattan State Hospital, East, to represent the State hospitals; Dr. Frederick Peterson, President of the Lunacy Commission, a member *ex-officio*.

All of the appointments to the Advisory Board are permanent except two. The two superintendents of asylums on the board were elected by the fourteen asylum superintendents of the State at a meeting held in Buffalo, September 28, for a term of two years only, thus permitting all of the asylums to be represented in rotation on the board.

All of the gentlemen selected have accepted their appointments. They serve the State without charge, willingly giving their time and services free for the cause of science, and to advance the interests of the insane.

The Population of the United States.—According to the census of 1900, the population of the country is 76,303,387, an increase since 1890 of 13,233,631, or 21 per cent. The excess of males over females is 1,815,097, the males outnumbering the females in all but eleven of the fifty-two States and Territories. These eleven States and the excess of females in each are as follows: New Hampshire, 830; Massachusetts, 70,398; Rhode Island, 7,524; New York, 39,334; New Jersey, 149; Maryland, 3,581; District of Columbia, 14,710; Virginia, 2,390; North Carolina, 16,456; South Carolina, 10,526; Georgia, 9,029. The excess of males in California is 156,009, in Minnesota, 113,586, in Texas 109,090, and in Pennsylvania 106,967. The excess of females in the Southern States is largely made up of negroes, of which race there are in the whole country 54,347 more females than males, North Carolina leading with an excess of 17,221, closely followed by Georgia, South Carolina, and Virginia, and the District of Columbia in the order named. A comparison of the relative increase of whites and negroes during the decade shows a slight falling off in the latter, the increase for the whites being 21.4 per cent. against 18.1 per cent. for the negroes. This relative decrease holds good in the Southern States as well as elsewhere, showing that the whites in that section have increased in greater proportion than those of negro descent.

Obituary Notes.—Dr. ALFRED C. LEMBERGER of Louisville, Ky., died suddenly on October 11, of heart disease. He was a graduate of the Louisville Medical College in the class of 1893.

Dr. HIRAM TUTTLE of Tacoma, Wash., died suddenly at his home in that city on October 9. He was born in Iowa in 1844, and was graduated from the Medical Department of the University of California in 1869. He was the discoverer, a few years ago, of the explosive thorite, for the purchase of which Congress made an appropriation at its last session. He practised medicine in Tacoma for nine years, having settled there in 1889, retiring in 1898 in order to devote himself to the perfecting of his discovery.

Dr. SAMUEL EDWARD STILES, a homœopathic practitioner of Brooklyn, died on October 9 at the age of sixty-seven years. He was a graduate of the Long Island College Hospital Medical College in the class of 1870. He was one of the incorporators of the New York State Genealogical and Biographical Society.

Dr. R. H. NESBITT of Wheeling, W. Va., died on October 10, at the New York Hospital, of strangulation of the intestine. He was a graduate of the Medical Department of Columbia University in the class of 1899, and then served as interne in the New York Hospital. After completing his term at the hospital he went to Europe and had just returned when he was seized with his fatal illness.

Dr. DONALD R. HINCKLEY was killed on October 14 by the accidental discharge of a revolver he was handling, during a visit at the house of his father in Northampton, Mass. Dr. Hinckley was a graduate in arts of Yale in 1892, and in medicine of Harvard in 1896. He was a resident of New Haven and an instructor in the Yale Medical School.

Dr. JOHN B. EVERHART died on October 8, at West Chester, Pa., at the age of seventy-four years. He was a graduate of Princeton and of the Medical Department of the University of Pennsylvania, but he never engaged actively in the practice of medicine. During the Civil War he was surgeon of the 97th Pennsylvania Volunteers.

Correspondence.

OUR LONDON LETTER

(From our Special Correspondent.)

SMALLPOX—TYPHOID FEVER IN SOLDIERS' KITS—SHORT WATER SUPPLIES—NEW ANATOMICAL DEPARTMENT AT GLASGOW—JAMESON'S PORTRAIT—SMALLPOX SPREADING—OFFICIAL ACTION AND OPPOSITION—WATER SUPPLY IN THE NORTH—PAGET'S LIFE—COMING SESSION—RECENT DEATHS.

LONDON, September 21, 1901.

THE smallpox outbreak is not yet stamped out. On Saturday, two fresh cases were notified, bringing the number of admissions up to 134, since increased to 140. Maidstone has been alarmed and not without reason. It transpires that the patient I mentioned as having gone there and died was not suspected at first to be suffering from smallpox. He traveled in an ordinary way by rail, and then took a cab. He was afterward admitted to the hospital, and placed in the general ward. Precautions were taken there, but the railway compartment was not identified, and it is said the cab was next day used at a wedding.

A number of hop-pickers have gone down into Kent as usual to reap their little harvest, and one of them, with his child, has been admitted to the Malling Isolation Hospital with smallpox. In spite of active precautions, the danger there is considerable on account of the large number of pickers concentrated in shelters. Many are being vaccinated.

The stress of the epidemic is still in the parish of St. Pancras, and on Wednesday a meeting of the Guardians was held on the demand of the Local Government Board, which sent Dr. Sweeting to make representations. The doctor said that of 147 reported cases 100 had come from their parish, where the disease is still spreading. He called upon the Guardians to afford additional facilities for vaccination and accused them of being dominated by one individual member of the board who was an anti-vaccinationist. He told them that if they did not do their duty, they could be compelled by mandamus. He also told them they had no right to summon before them the parents who had neglected to have their children vaccinated. That was usurping magisterial authority. The vaccination officer must summon such people before a magistrate independently of the Guardians. This produced some effect, for the board decided to open a public vaccination station and appoint an assistant vaccinator and additional officers.

A case has been reported in the Borough of Southwark, in a common lodging house, where 100 men sleep who are daily employed in the market. In the dormitory, where the case occurred thirty beds were all occupied. The medical officer has had the dormitory closed, the beds burned, and the room disinfected.

The Local Government Board has issued a circular to

boards of guardians after consulting with the law officers of the Crown, pointing out the proceedings to be taken with a view of procuring the vaccination of a child, and showing that certain supposed difficulties do not exist. They say, too, significantly, that when objection is taken to proceedings antagonistic to the views stated in the circular, the justices should be made aware of their opinion thus expressed, and of the fact that the opinion is based on the advice of the law officers of the Crown. It is well to find the Government Board thus alive on the matter.

As to the mortality, nine deaths from smallpox were registered last week in London, but none in the thirty-three great towns. The cases remaining under treatment numbered one hundred and thirty-five. There were sixty fresh ones admitted as against thirty, fifty-two, and thirty-one in the preceding three weeks.

Since 1885 the deaths from smallpox have not exceeded 100 in a year, except in 1893. Last year the cases of the disease were rather more numerous, and epidemiologists looked for a series of recurrences followed by a decline. An increase of severity, too, may be expected, but already some of the cases have been of the hemorrhagic type. Perhaps our greatest peril is the large number of unvaccinated children and their aggregation in schools. It is estimated that from 25 to 35 per cent of the children born in London for the last few years are "unaccounted for" in this respect, and in some districts the percentage is much higher, as much as 60 and 70. Mild cases coming to school in such conditions are certainly a great danger. The anti-vaccinationists have a terrible responsibility, and the weak-kneed government that lessened protection to secure their votes may well reflect on their folly.

A case of typhoid has occurred which seems to have been traced to the wearing of clothes sent home from South Africa to the family of a soldier who died there of the disease. Of course, it is possible that this case might have been contracted otherwise. But it is equally possibly the inference has been correctly drawn, and it opens the question of the propriety of returning a dead soldier's kit to his family. Certainly, when he has died of infectious disease, precautions ought to be taken.

Manchester is threatened with a water famine. A few showers have encouraged the inhabitants, but a heavy downfall is necessary. The stock of water in the corporation reservoirs has fallen to about twenty-four days' consumption. The works at Thirlmere were expected to give a supply of 50,000,000 gallons daily, but as yet have only yielded 8,500,000, and new pipes are being laid as rapidly as possible. Since July 21, the water has been cut off from 8 P.M. to 5 A.M. It was then reckoned that enough for forty-nine days was secure. The hot and dry season has put up the consumption, and after sixty-six days the amount has fallen to a supply for twenty-four days; and the supply is so divided that a shortage in one part may be complete famine in another.

Nor are Manchester and its surroundings alone in their anxiety. Many parts of the country have been exercised about this aspect of the hot summer. From Wales, usually so well supplied, come complaints of discolored water due to the peaty soil of the gathering grounds and imperfect filtration on account of the drain on the storage reservoirs.

Lord Lister opened the new anatomical department of Glasgow University on the 12th inst. The new buildings include a laboratory and museum. For the latter, Professor Cleland has presented his anatomical collection. Lord Lister congratulated him on the accommodation now provided.

Surgeon-General Jameson, late Director-General of the Army Medical Department, is to have a further testimony of the esteem in which he is held. A committee has been formed to present him with his portrait, and if funds permit replicas will be presented to the R. A. M. C. messes of Aldershot and Netley.

London, September 27, 1901.

Smallpox has steadily increased during the week, and several fresh centers have become infected. Yesterday added nine fresh cases; the previous three days having returned five, five, and eight. The fresh districts infected include Hackney, West Ham, Shoreditch, Woolwich, Bromley and Beckenham. Two villages in Norfolk have also been infected, each by a London visitor.

Altogether there have been 200 notifications during the outbreak. Of these, ninety-five were in St. Pancreas, where the disease first broke out, thirty-eight in St. Marylebone, and sixteen in Holborn. The number of patients now under treatment in the hospitals is 172. As to the mortality, three deaths appear in the Registrar-General's returns for last week. The previous week there were nine. Altogether thirty-one deaths have been registered during the last thirteen weeks.

As to age, a return from St. Pancreas shows that one case was a child under five years, six were children between five and ten, and seventeen between ten and fifteen. Of the remainder, six patients were between fifteen and twenty-five, and thirty-five between twenty-five and sixty-five.

Some schools have been closed, and in others visitors have been excluded. Facilities for vaccination have been extended—not without raising the spleen of the anti's.

Permission to search for the unvaccinated among children attending board schools in any area affected by smallpox was on Monday conditionally, I may say grudgingly, granted at a meeting of the school board. The point was raised in the form of various communications from the local authorities and the Local Government Board, and two hours were wasted in disputation. A member actually proposed to refuse such permission, and to give an assurance that they would prevent the disease spreading in schools. A more sensible member proposed that unvaccinated children should be excluded from the schools until they had complied with the vaccination acts, but he found no seconder. What a revelation of the fitness of the board to have charge of the education of the people! Eventually, by nineteen to sixteen votes, permission was given to inspect the schools "with a view to advising the parents to allow their children to be vaccinated;" but this is to be conditional upon an application from the proper authorities, and upon the "issue by the school board of a circular to all parents asking if they have any objection to this examination, and in case of such objection in any particular case that no examination shall take place."

And so a board entrusted with the training of the children deliberately throws difficulties in the way of officers desirous of carrying out the law. No wonder lawlessness increases!

Some local authorities are giving better object-lessons. Thus in Hackney, which was among the places to provide free vaccination before the passing of the acts, they are now paying the inhabitants of some infected houses to isolate themselves by staying indoors and not sending their children to school. In Southwark, they have issued a circular stating the early symptoms of the disease, and advising any one ailing from them to consult the medical officer. An alderman has addressed a letter to the press advocating a similar action throughout London. In Camberwell the Guardians' Home refused the request of the school board to convey its resolution to their vaccination officers.

The Local Government Board is giving full support to the sensible and warning to the recalcitrant bodies. On Wednesday they issued three circulars to the sanitary authorities, boards of guardians, and borough councils directing them on various points as to their duties in face of the prevalence of smallpox, and enjoining them to adopt every precaution, dwelling specially on vaccination and the advisability of house-to-house visitation in affected districts.

But do not imagine the anti's are abashed. They cry no surrender and carry on a guerrilla war against science, sense, and statistics. One of their methods is to urge people to seek certificates of exemption. Some magistrates, even when granting these, have warned the applicants of the risk they were incurring. Some have postponed the issue of a certificate a few days, and advised the applicant to consult his doctor.

A public meeting is being called by the anti-vacs, and they expect Dr. Collins will preside. He has long been heterodox about vaccination, and so had no difficulty in obtaining influence among the cranks. It is curious how a man who did pretty well as chairman of the County Council should have such a queer mental twist.

The water supply is continuing to give anxiety in the North of England. The scarcity is being felt over a wider area. Leeds and Bradford are economizing water. Dewsbury and Keighley are restricting the hours of the supply. At these and other towns, a fortnight's further dry weather would render the position acute. At Huddersfield, mills on the high level will have to cease work unless copious rains speedily fall. Some firms have had to suspend business at Heckmondwike for want of water, and other places will have to follow from necessary curtailment of the supply.

The publication of the "Memoirs and Letters of Sir James Paget" on Wednesday was a literary event which had been waited for with great interest in the profession. The early part is autobiographical and in the fascinating style of our late leader. The remainder is by his son Stephen and is largely built up on his father's letters.

Next week the schools will open with a flood of eloquence and good advice and a deluge of after-dinner speeches. For dinners are more and more displacing the

introductory lectures. The teachers are all back from their holidays and speculating as to the likelihood of a good entry.

Another octogenarian has passed away, Dr. Douglas, of Chesham, in his eighty-third year. Other recent deaths are: W. Luke Roberts, senior surgeon to Bradford Infirmary, on the 8th inst., in his fifty-sixth year; F. B. Archer, on the 20th, aged fifty-four; Lt.-Col Moran, M.D., on the 20th; Dr. J. O. Bradbury, consulting surgeon Salford Royal Hospital, on the 5th inst., aged seventy-two.

Progress of Medical Science.

The Boston Medical and Surgical Journal, October 10, 1901.

A Case of Intussusception; Resection of Fifty-six Inches of Small Intestine; Recovery.—F. G. Balch reports the case of a girl of sixteen years, who, after a most injudicious repast, suffered from intussusception, which upon incision was found to be jejunum into ileum. There was free purulent fluid in the abdomen and the mass looked so bad that the intestine was resected and brought together by end-to-end anastomosis. There was considerable shock, with some delirium and restlessness, but recovery was good. The bowels moved regularly and the fifty-six inches of small intestines did not seem to be missed at all. Examination of the resected gut showed a polypus almost completely filling the lumen of the bowel, which was undoubtedly the cause of the intussusception.

Cretinism.—Charles S. Millet gives Osler's definition of cretinism as a "chronic disease of nutrition due to loss or impairment of function of the thyroid gland. It causes a retardation of development of the central nervous system, leading to a retention of an infantile state and to an extraordinary disproportion between the different parts of the body." The author describes the various symptoms in detail. Early and slight forms, he says, are often overlooked; the mental apathy, muscular weakness, stoppage of growth, dryness of skin, together with subnormal temperature, are enough to justify an experimental course of treatment with sheep's thyroid. This is best given in powder, as it dissolves rapidly on the tongue, and none is lost, even if the patient is unruly. It is best to begin with half a grain three times a day, and gradually to increase it. Whenever the temperature goes above 100°, or the child becomes very nervous and does not sleep, the remedy must be diminished or stopped for awhile. Later, when the nutritive changes are fully reestablished, a very moderate dose once or twice a week will be sufficient.

Hernia Reduced "En Bloc"; Operation and Relief of Internal Strangulation.—C. A. Porter reports a case in which the symptoms after reduction by taxis remained so severe that a diagnosis was made of reduction *en bloc* (the sac with its contents being pushed entirely beyond the inguinal canal into the submuscular space), and a rapid abdominal section was performed. On walling back the intestines, the distended ileum could be seen to enter a peritoneal opening opposite the internal ring, and collapsed and pale intestine emerged from the same aperture. Upon slight traction a short knuckle of intestine popped out, showing well a distinct sulcus where constriction had occurred. Gas immediately filled the previously collapsed portion, and the dark purple color changed to normal pink. The empty sac was found to lie in the subperitoneal tissue, entirely within the muscles and in no relation to the internal ring or inguinal canal. The case was then one of inguinal hernia, which, as there were no or only slight adhesions between the sac and surrounding tissues, had been converted by manipulation into the so-called "properitoneal or interstitial variety." On the left side the sac was found to be inverted, and to its tip a coil of intestine was firmly adherent. Both sacs were tied off and the abdomen was closed. The patient's condition did not warrant operation for radical cure. Recovery was uneventful, and a month later both hernial openings were operated on.

New York Medical Journal, October 12, 1901.

The Social Aspects of Dermatology.—In the fifth Lane Lecture, Malcolm Morris takes up the discussion of tuberculosis, scrofula, and lupus. Although admitting that the term scrofula has somewhat gone by, he finds it a useful one by which to designate a special delicacy of tissue, making it vulnerable beyond what is seen in the healthy state to injurious influences of all kinds. Scrofula may prepare the way for tuberculosis; or, rather, it is the soil, the bacillus the seed, and tuberculosis the harvest. Lupus vulgaris he regards as a chronic form of tuberculosis. Carcinoma may develop on a lupus lesion, and this fact must be borne in mind in making a prognosis. These secondary carcinomatous growths are apt to be especially malignant. Lupus may be transmitted by vaccination. It generally begins by direct inoculation of the tubercle bacillus in the cracks and fissures of the nose or mouth. Secondary tuberculosis of the lungs may develop from a primary lupus nodule in the skin. Tuberculides are characterized as lesions consisting of small extremely indolent granulomata tending to undergo central softening and death, and thus leaving scars.

A Case of Peliosis Rheumatica (Schoenlein's Disease).—Fairfax Irwin reports the case, which was that of a man of twenty-nine years, first seen three weeks after the initial symptoms—œdema of the hands and pain in the phalangeal and metacarpal joints—had manifested themselves. The same condition later attacked the feet and knees. Ptyalism developed with spongy gums, loose teeth, and ulcerations of the buccal mucosa, coincident with a purpuric eruption covering nearly the entire body. The patient recovered without incident. Diagnosis in such cases must be made between this condition and scurvy, purpura hæmorrhagica, and possibly syphilis. While there was some enlargement of the inguinal glands, syphilis was ruled out on account of the absence of chancre, and the rash was distinctly not syphilitic in appearance. The ptyalism was doubtless due to some medicine taken before the man fell sick, and which probably contained iodide of potassium and mercury. Scurvy was excluded, as there was no difficulty in regard to securing diet of fresh vegetables. The predominance of the œdema and the rheumatic symptoms led to a diagnosis of peliosis rheumatica rather than purpura.

The Growth of New Bone from Periosteum.—J. H. Branth gives the histories of one or two cases illustrative of the fact named in the title of his paper. He says that injuries to the periosteum will often cause a necrotic condition of the underlying bone of more or less depth until the inflammatory condition and its walls form a barrier against further invasion. Quietude and healing in the part do not set in until the dead matter is ousted from the body; the dead matter, having reached the surface of the bone, often finds an especial resistance in the periosteum, and, as a consequence, the periosteum, besides becoming involved in the inflammatory process, is then dissected up farther from the underlying bone by the pressure of the abscess matter. Now, more bone surface is denuded and deprived of one source of nutrition, that of the periosteum, and the pyogenic germs find less resistance in the half-starved living part, the *locus minoris resistentiæ*, and more or less of the bone is involved before the inflammatory process can make its way out through the periosteum, which latter has the greater vitality. In this way it may occur that, after necrosis of a part of a bone, the periosteum, having been lifted off the bone, may deposit osseous cells on its lower surface, and so build a bridge, as it were, over the necrotic substance for some distance, while at some small outlet the *débris* makes and finds its exit. The internal dead bone is the sequestrum and the newly formed bone is the involucrum. Such a condition will not permit healing until the sequestrum is removed, which Nature alone accomplishes by a slow disorganization into *débris* unti it is removed through the avenues of exit.

Journal of the American Medical Association, Oct. 12, 1901.

A Plea for the Backward Child.—C. F. Wahrer makes a plea for the so-called dull children, claiming that, while they are not so attractive to the teacher as are the brighter children, yet the after-history of the two classes often shows that the former achieve much more in life than the latter.

Some Suggestions Regarding a Department of School Hygiene.—L. K. Hunt makes a plea for greater interest on the part of the public in all that concerns public-school hygiene. This latter term now has a wide meaning, including reference to diseases common to school age, hygiene of instruction, personal hygiene of pupils, school grounds, physical education, buildings, including furnishings, ventilation, sewerage, heating, etc. All such matters should be entrusted to "men of mature judgment, but an age limit, say fifty-five, should exist. They should have a vital connection with the schools through having children therein. They should be men of assured executive ability through having succeeded in business. They should not be known as local politicians. These matters are emphasized, because the school board is the snag on which such reforms usually stick, and because physicians, through combination with other organizations of good citizens, can materially assist in the election of an effective school board." In other words, these matters should be taken out of the hands of teachers and entrusted to those who have more time and greater practical knowledge of the matters involved.

Speech as a Factor in the Diagnosis and Prognosis of the Backward Child.—G. Hudson Makuen concludes his

paper as follows: 1. It is not always possible to determine at a glance the cause of backwardness in children. 2. Backwardness in children is not always due to a central lesion, but may be the result of arrested cerebral development due to some abnormality of structure in the peripheral organs. 3. A very common cause of backwardness in children may be some abnormality of structure in the peripheral organs of speech. 4. So closely are the speech centers related to the ideational centers of the brain that any impairment of the one generally results in a corresponding impairment of the other. 5. The best method of arriving at even a proximately correct prognosis in cases of backward children is to apply the speech test, or, in other words, to ascertain by careful study and experiment to what extent the faculty of speech may be improved, and it will be found that in those who are susceptible to training in what may be called the refinements of speech are the ones for whom we may promise the best results, and that possibilities for general development will be proportional to the capacity for speech development

Diagnosis of the Backward Child.—Among the practical points mentioned by A. W. Wilmarth are the following: Of the physical symptoms which are strongly indicative of lack of normal mental growth, the failure of articulate speech, where defect of the auditory apparatus, or that concerned in articulation does not exist, is the most conspicuous In the absence of these physical defects, if the appearance of speech is delayed beyond the age of six years, it may be safely inferred that cerebral deficiency or lesion exists, and that some mental weakness surely accompanies the child's silence. Gait and posture are of some value, taken in connection with other symptoms. The former is apt to be slow and awkward, the latter stooping. The lately published observations of Wiley would tend to show that the sense of touch is generally less sensitive than in the average child. Sensibility to pain, especially in cases of marked dulness, is very frequently found, and would tend to indicate a lack of tone in the whole nervous system. Family history will render valuable aid. As all mental action has a physical basis, and as the physical formation of each individual is but the sum total of ancestral traits, we may expect parental weakness to exist, either active or latent, in the offspring. Again, while a fair memory by itself is no indication that mental weakness or delayed mental growth is not present, a failing memory, or one that fails to respond to training by any marked improvement, may be looked on as abnormal.

American Medicine, October 12, 1901.

Uric-Acid Fallacies.—Frank Billings declares that some of the fallacies of uric acid are: 1. That uric acid is toxic. 2. That it is a causative factor in any disease except gout. 3. That "uricacidæmia," meaning acid blood, exists. 4. That the chemical reaction of the blood may be altered by the use of medicinal quantities of the alkalies or by diet. 5 That uratic deposits may be dissolved out by the administration of alkalies. 6. That lithia is a uric-acid solvent of unusual potency. 7. That uric acid is an abnormal constituent of the urine. 8. That an excess of uric acid in the urine at one time or a deficiency at another time indicates an abnormal condition in reference to uric acid. 9. That rheumatism is due to uric acid. The writer adds that our present position in relation to uric acid consists not so much in positive knowledge as in the throwing aside of an accumulation of old theories and absurdities.

Kidney-Stone Diagnosis and Treatment.—Donald Macrae Jr., speaks of the following aids to the diagnosis of probable stone in the kidney: General symptoms, local and reflex; examination of the urine, chemical, macroscopical, and microscopical with the centrifuge; percussion over the affected side; the ureteral catheter and sound; inspection of the bladder and ureteral orifices; the segregator. He then turns his attention to the discussion of the x-ray as a positive means of diagnosis, quoting from Dr. Leonard his routine technique. A plate sufficiently wide to cover both lumbar regions is used. The plate is protected from moisture and heat, and is placed beneath the patient supported by a heavy board. Both kidneys and ureter are examined at the same time. The tube is in the median line above the third lumbar vertebra and high enough so that its rays pass through the pelvis and cast a symmetrical shadow of the pelvic outlet on the plate below. A grounded piece of sheet aluminum or gold-leaf on cardboard is placed between the tube and the patient. As to treatment, the disease is surgical. If the trouble has been of short duration and the symptoms are not very urgent, nature should be given a chance. If the urine is strongly alkaline, however, even if the symptoms have not existed very long, operation is advisable. The writer believes that it is the duty of every surgeon to subject every case of an affection pointing to a pathological nephroureteral condition to the x-ray. There may be a few exceptions in cases of nephritis following the exanthematous diseases, but even here, if the condition continues, the possibility of secondary calculi must be thought of.

Philadelphia Medical Journal, October 12, 1901.

The Progressive Muscular Atrophies.—Edward E. Mayer enumerates the three general forms of progressive muscular atrophy that have been recognized; in one the muscular changes are primary—the myopathic form or progressive muscular dystrophy; in one they are secondary and due to changes in the anterior horns—the myelopathic or amyotrophic form, or spinal muscular atrophy; in the third the primary degeneration is in the peripheral nerves—the neurotic or neural type. Although this classification is simple and convenient, it is not always either clinically or pathologically true. There are transitional and mixed types. Of these the writer gives several examples, one of which is as follows: The patient was a boy of eighteen years who had extensive atrophy and paresis of a slowly progressive nature. The alterations were general, embracing chiefly the shoulder-girdle, pectorals, triceps and biceps, supinator longus, interossei, thenar and hypothenar muscles, erectores trunci, abdominal muscles, gluteals, gastrocnemius, and peroneals. The atrophy was symmetrical. There was fibrillary tremor There was no reaction of degeneration. This disease, so far as could be learned, was not hereditary. There was no history or sign of true or pseudo-hypertrophy. This case must be regarded clinically as one of a mixed type, and more of a dystrophy than an atrophy.

A Case of Tuberculous Ulcer of the Stomach.—Erwin Fischer states that Petruschy's case is the only one besides his own which is reported in literature. Fischer's patient was a young lady, twenty-three years of age, with a suspicious family history of tuberculosis. She complained of fulness after eating, and of occasional pains in the epigastrium, and extreme weakness. There was no sign of disease of the respiratory organs excepting a slight roughness of the respiratory murmur over the right apex. There was HCl acidity, about 2 per cent. Treatment consisted in the administration of Carlsbad salt internally with hot local applications. The improvement was slight, and later nitrate of silver was administered. This seemed to aggravate the symptoms. Electricity was tried in vain. Some months later the patient began to lose flesh and suffered pain always after eating. The original treatment was given again with the same result. Tuberculin was then tried, of which the second and third injections (5 mg. each) produced typical general and local reaction. The local reaction was evidenced by increased pain in the gastric region, followed by nausea. The pulmonary symptoms were so slight that the lungs could scarcely be claimed as the seat of the primary lesion The regular treatment with tuberculin R was given, and the doses were gradually increased to 20 mg. The condition now is practically that of recovery. The treatment will have to be resumed again after a few months.

The Lancet, October 5, 1901.

A Case of Sudden Death Eight Days after Amputation of the Forearm.—P. N. Gerrard's patient was a Chinaman who had severe injuries of the right hand, which had become septic, and amputation was deemed advisable owing to extensive disorganization as far up as the wrist. Owing to infected lymphatics, the amputation wound also became infected, but it was drained and the patient seemed to be doing well. Death came very suddenly, almost without warning. The cause of death in this case, which at first sight was diagnosed pulmonary embolism, is peculiar from the fact that, notwithstanding very careful search, no clot or embolus was found in any part of the lungs. The fact that the patient did not complain of any palpitation or distress until a few minutes before dissolution, when he remarked before falling back in his bed that his "breathing was difficult," considered in connection with the finding of a clot (small in diameter) partly in the right auricle and extending into the ventricle, leads the author to the conclusion that the immediate cause of death was cardiac syncope consequent on the disturbance of an ante-mortem clot which had formed in the right auricle, as a result of septicæmia, from which at the date of his death he had recovered —or, in other words, he died from cardiac thrombosis. It furthermore raises the question as to the advisability of exhibiting alcohol freely in all cases in which operations cannot be done promptly, and in which septic absorption is probable, in order that no slowing of the circulation and consequently no deposition of fibrin may take place in the right auricle.

Morvan's Disease or Leprosy.—Morvan's disease has been regarded by many writers as a form of syringo-

myelia, while others regard it as nothing but leprosy modified by environment. D. Douglas-Crawford records the history of a case of what he would regard as Morvan's disease. His patient was a man of twenty-seven years who had worked in a lime quarry. The local changes were somewhat suggestive of leprosy, but the nerves were not nodose, the reflexes were exaggerated, whitlows were limited to the fingers, and there was hydroarthrosis of one shoulder joint. The latter was considerably disorganized, the digits of both hands showed signs of mutilation, but the thumbs, the little fingers, and the right ring finger had not suffered. As regarded the nervous system, speech was slightly indistinct and slurred, but the taste was unimpaired. The patient could protrude his tongue, but could not move it laterally. The pupils reacted to light and accommodation, there was no limitation of the field of vision, and no nystagmus. There was right external strabismus of many years' standing. If the patient closed his eyes while standing up he toppled over. The muscles of the left thumb was slightly wasted. Sensation to pain, heat, and cold was greatly impaired over the skin of those digits which were supplied by the median nerve. The other skin areas were fairly normal. Tactile sensation was normal throughout both limbs; the muscular sense was unimpaired, but a tremor of the limbs was noticeable on attempts being made to use them. The knee-jerks were exaggerated, the plantar reflex was present, and ankle clonus was well marked. The gait was slightly spastic. Sensation to pain, heat, and cold was impaired over the outer sides of the upper thirds of both thighs and also over the dorsal surfaces of the feet. Sensation in the cervical region was normal except over the area supplied by the right small occipital nerve.

An Interesting Case of Compression.—E. J. O'Meara narrates the history of a man of twenty-six years who was struck over the head with a club. Twenty-seven hours after the injury he was admitted into the hospital in the following condition: Slow regular and heaving pulse, the pupils were dilated and non-responsive, there was retention of urine, paresis was more marked on the left side, and there was deep coma; no fracture could be made out, and the condition was considered one of subdural hemorrhage. Trephining over the anterior branch of the right middle meningeal artery revealed a large clot, but the artery was uninjured. A similar condition was noted when the posterior branch of the same artery was exposed, but the artery here was also intact. As the hemorrhage from the latter opening was profuse, the opening was enlarged and the finger passed backward toward the occipital region; it then became evident that the whole of the posterior part of the brain was compressed by a large clot. Five and a half ounces were scooped out with a spoon, the brain expanding as the blood was removed. Long strips of gauze were rapidly passed into the cranium between the dura and the bone, the ends being brought outside with the twofold object of acting as a drain for the hemorrhage and of minimizing as far as possible the danger of spreading œdema from a too rapid expansion of the compressed brain. Immediate and eventual results were excellent, the patient becoming as well as ever. The author records the case, as there are many interesting points, especially as regards the history and the extraordinary length of time before definite symptoms of compression appeared, and the absence of any very definite symptoms to enable the seat of injury to be localized. He has not been able to find on record any other case in which plugs have been successfully used in the extradural space with the objects of (1) acting as drains for the excessive hæmorrhage, it being impossible to localize or to reach the bleeding point, and (2) of exerting some pressure on the expanding brain. In this case the compression was so great, and extended over such a large area of the brain surface, that *a priori* it is very doubtful whether without some means of this kind the patient would have escaped the danger of spreading œdema.

British Medical Journal, October 5, 1901.

A Case of Erysipelas Treated with Antistreptococcus Serum.—H. W. Haydon reports the case of a man aged forty years who had an attack of cellulo-cutaneous erysipelas. He treated him with injections of antistreptococcus serum. After each injection the improvement was marked.

House-Flies and Disease.—Colin Campbell believes that flies play a far more important part in the spread of infectious diseases than is generally believed. He thinks that this may be the way in which diphtheria is often spread. He reports the case of a child who was infested with eggs and larvæ of the common house-fly.

Case of Complete Atresia Vaginæ and Absence of Uterus.—Leslie J. Milne describes this case. The patient was a woman aged thirty-four years. She consulted the writer for a slight dyspeptic attack. He discovered casually that she had never menstruated. Examination disclosed not only that the vaginal opening was entirely wanting, but that there was no uterus. There were only some rudiments of the appendages. Any intercourse she had had was through the urethra, and had been only very partial and painful.

Case of Membranous Dysmenorrhœa in a Multipara Associated with Membranous Colitis. G. Ireer Carter reports this case, the association of the two affections being undoubtedly accidental. The case is quite unusual. A striking feature of the case was that the patient was not sterile. The symptoms were abdominal pain and tenderness in the left iliac region, and in the course of the large bowel. Constipation was troublesome. When the intestinal attack was coincident with menstruation, the sufferings were severe. In the intervals between attacks, the patient looked fairly well.

Notes on Enteric Fever at the Imperial Yeomanry Hospital, Pretoria.—H. D. Rolleston declares that, although the typhoid fever met with in South Africa differs in some respects from the disease as it is seen in England, still the resemblances are so close that there is not the slightest doubt of their identity. A previous attack of the fever in another country, even in South Africa itself, does not necessarily protect the individual from another attack in South Africa. Statistics seem to show that antityphoid inoculations do not absolutely protect against a future attack of the fever. When typhoid fever occurs in an inoculated person, there is, as a rule, an interval of at least six months before a second attack occurs. Inoculation protects against a fatal termination of the disease. The percentage of relapses is estimated at twenty-one. In some of the cases, the onset was quite sudden. Diarrhœa was decidedly exceptional. Constipation was the rule. In many cases there was a rapid pulse-rate during convalescence. Considerable hemorrhage of the bowels occurred in 8.7 per cent. Perforation occurred in only one case. Phlebitis was the commonest sequela. Neuritis was seldom seen. Epilepsy occurred in one patient. Insanity was rare. Bronchitis was rare. Pleurisy was not uncommon. Arthritic sequelæ were met with, as were myositis, periostitis, parotitis, orchitis, and epididymitis. There was one case of jaundice, and also one of multiple abscesses.

Medical News, October 12, 1901.

The Crowding of Consumptives into Municipal General Hospitals.—William Ridgely Stone sounds a timely warning on this subject. In one of the wards of a municipal hospital having the capacity of twenty-eight beds, over forty patients are placed. More than twenty of these are tuberculous. These patients are, as a rule, not intelligent enough to understand the danger to which their companions are constantly exposed. They will not use the sputum cups, but expectorate on the floor, on the bed clothes, or into the registers. This last-named receptacle seems to be a favorite one. The results need not be described. The writer goes on to relate the history of various patients who, admitted to the hospital for other troubles, have contracted this dread disease before they went to their homes.

Berliner klinische Wochenschrift, September 23, 1901.

Oxygen Inhalation.—E. Aron has for eight years been making observations on the effect of oxygen inhalations in health and various forms of disease in which dyspnœa is a prominent factor. These investigations, as well as experiments on animals, lead him to believe that there is no advantage to be derived from the use of oxygen inhalations except in cases of carbonic acid or ammonia poisoning, and in diseases resulting from the action of rarefied air.

The Stretching of the Kyphos in Pott's Disease.—Jacques Joseph advocates forcible extension of the deformed spine in this condition, and describes a specimen of Virchow's and a case of his own to demonstrate the manner in which the bony gap left after the operation is filled in. This takes place by a gradual descent of the upper part of the trunk, thus wholly compensating for the defect without the formation of more than a few millimeters of new bone. The apparatus devised by the author consists of a brace provided with a screw and pad to fit over the boss of the kyphos, by means of which graduated pressure can be made. The advantages of this device over the plaster jacket are that (1) extension and fixation are accomplished successively and not synchronously; (2) the pressure may be accurately graduated, and the spinal column can therefore be brought more exactly into the desired position; (3) changes in position may be effected without the manufacture of a new corset; (4) the extension takes

place very gently; so the formation of pressure sores may be more carefully guarded against, and when such occur they immediately present themselves to view.

The Etiology of Lymphatic Leukæmia.—W. Turk considers Lowit's theory of the parasitic origin of lymphatic leukæmia, and describes some observations he has made which explain the appearances figured by the latter. The hæmatoblast leukæmiæ parva intracorpuscularis of Lowit is a small rounded or oval body occurring especially in degenerated leucocytes, and from one-sixth to one-half the diameter of a red blood cell. Usually only one or two forms are found in a single cell, and the centre of the organism is apt to be lighter than the periphery. In order to demonstrate it, a rather uncertain staining method is necessary. After fixation by heat, the smears are stained with a strongly alkaline and polychrome solution of methylene blue, and heated while in the fluid for about fifteen minutes. They are then washed and decolorized with a $\frac{3}{10}$ per-cent. solution of muriatic acid (which is the most uncertain step in the process), and are counterstained with a ½-per-cent. watery solution of eosin. Turk repeated Lowit's observations, and then tried to find similar bodies in other conditions. By producing artificial disintegration of the leucocytes by pressure, he was able to demonstrate the same appearances in the blood in three cases of chlorosis, and so assumes that they are nuclear bodies. They do not respond to any stain except to methylenazur, a substance formed from methylene blue by treatment with hot alkali, and hence the Nocht-Romanowski stain for malaria is well adapted to show them, though they appear only when liberated from the cell body by its rupture.

Muenchener medicinische Wochenschrift, Sept. 24, 1901.

Pruritus Senilis Linguæ.—E. Baumgarten describes a case of senile pruritus, which first manifested itself in the tongue and was treated without relief for some time before the true nature of the trouble became evident, through the occurrence of itching elsewhere. This condition is so rare that the diagnosis is justifiable only after all other possibilities have been inquired into and excluded. There are many systemic conditions capable of producing subjective symptoms in the tongue without visible lesion, but nearly all of these may be relieved by appropriate treatment, while true pruritus is not amenable to remedial measures. The more important of such causal conditions are affections of the stomach, intestines, liver, kidney, and spleen, all circulatory disturbances, and trouble with the pelvic viscera, especially in women about the climacteric.

Tamponade of the Abdominal Cavity with Air for the Checking of Dangerous Intestinal Hemorrhage.—G. Kelling's experiments on dogs lead him to conclude that by inflating the abdominal cavity with air it is possible to check hemorrhage from the stomach and intestines, originating in ulcerations, cirrhosis of the liver, etc. It was determined that a pressure of fifty millimeters of mercury was sufficient to overcome the resistance of the vessels, and also that such a degree of tension could be produced in the abdomen without danger. By combining endoscopy of the abdomen with injuries done to the viscera after inflation of the peritoneal cavity, it was seen that under such circumstances hemorrhage was very slight, while it immediately became severe as soon as the air was allowed to escape. The author has not yet been able to give the method a trial in man, but describes an apparatus consisting of a trocar, air filter, mercury manometer, and bulb for inflation, suitable for practical use.

A Case of Perforative Peritonitis Cured by Operation.—Brunotte's patient was a man of thirty-six years, who was kicked in the abdomen by a horse. He continued at work for three-quarters of an hour, at the end of which time he collapsed. During the next few days his symptoms presented the picture of a perforative peritonitis, but operation was steadily refused until the fourth day, when the patient was almost *in articulo mortis*. In spite of the shock of transportation for a distance of over five miles to the hospital, the laparotomy was recovered from, although it was found necessary to remove most of the sutures on the second day, owing to the great tension caused by the abdominal distention. On opening the abdomen, a considerable amount of foul pus was evacuated, and after as thorough a toilet as possible, the wound was partly closed and drained with gauze, but no attempt was made to find or close the perforation. A fecal fistula persisted and gave great trouble, owing to the exceedingly offensive diarrhœa, but finally closed spontaneously, and the patient was discharged seventeen days after admission.

Deutsche medicinische Wochenschrift, September 26, 1901.

Three New Cases of Pure Hereditary Ataxia.—E. Weber reports three cases of this affection which he considers above criticism. Three children in one family, aged respectively eighteen, thirteen, and seven, at the age of six developed typical symptoms of the malady consisting of ataxia of the legs, Westphal's sign, scoliosis, and chorea-like unrest. At the time of observation, the three individuals presented three stages of the disease, corresponding to the length of time of involvement. The oldest was in the last or paralytic stage, the next showed the disease fully developed, while in the last it was still in the early stages.

A Case of Tuberculous Arthritis of the Knee and Its Treatment with Tuberculin R.—Brunzlow was able to effect what appears to have been a permanent cure in a tuberculous knee affecting a boy of a markedly phthisical habitus. The following rules are laid down as a result of this experience: 1. Pronounced reactions are to be avoided in the use of Tuberculin R. 2. Even moderate elevations of temperature over the average prevailing before the injections were begun are to be regarded as reactions. 3. These manifestations must be allowed to subside fully before the next injection is made, as otherwise the system may be overcharged with toxin. 4. In the course of the treatment, reactions may be produced through rapid increase of dosage or the quick succession of slowly increasing amounts; under the latter conditions, the temperature rise is apt to be slight, but persistent. 5. Successful immunization is indicated by a permanent increase in body weight, which frequently takes place with surprising rapidity; systematic observations of the weight are therefore essential.

The Treatment of Dysentery.—A. Plehn's method is as follows. As soon as the disease has been diagnosticated, or is even suspected, the patient is given two tablespoonfuls of castor oil. This at once removes a large amount of infectious material and cleanses the intestinal canal. On the next morning the calomel treatment is begun. Every hour a tablet of ½ gr. of calomel is given until twelve tablets have been taken, when a pause is made till the next morning. The same plan is carried out on the second and third days, after which 8 gr. of subnitrate of bismuth are given at hourly intervals for twelve doses daily until recovery results. During the calomel course, and for several days longer, the mouth receives careful attention. After each dose of the drug, the mouth is rinsed with a wash of rhatany or salicylic acid, and any beginning tendency to salivation is combated by scrubbing the gums with swabs saturated with the above solutions. If these precautions are taken, the treatment rarely needs to be interrupted, and stomatitis occurs only in very unusual cases of idiosyncrasy. Any tendency to constipation, which sometimes occurs even before the calomel stage is over, should be met by the use of castor oil or enemas of salicylic-acid solution, while in the later days of the treatment, mineral waters may advantageously be employed. An important accessory is the proper regulation of the diet, which should consist wholly of fluids.

French Journals.

Lecithin of the Egg; Its Therapeutic Employment.—According to Coulombe, lecithin exists in all the tissues, especially in those endowed with great vitality. From a therapeutic point of view, it is not toxic, and it is assimilated as a whole in ordinary doses. Its action consists in increasing the number of red corpuscles; in increasing, in certain cases at least, hæmoglobin; in increasing urea and diminishing uric acid; in stimulating the appetite. Its employment is indicated in anæmia, in all troubles of nutrition, in wasting diseases, and in neurasthenia. It may be administered hypodermically or by the mouth. —*Le Mois Therapeutique, September* 30, 1901.

Psychical Troubles in Malaria.—Jean P. Cardamatis states that just as in the pathology of the nervous system, the toxins play the most important rôle, so it is not the malarial parasite, but the toxins which it secretes, which constitute the pathogenic cause of the various nervous phenomena observed in malaria. The delirium of malaria does not differ from toxic delirium. The intoxication of malaria may be pathological or psychological; there are four degrees: (*a*) excitation; (*b*) anæsthesia; (*c*) coma; (*d*) paralysis. There are three degrees of malarial delirium: Subacute, acute, and very acute. The writer believes psychic troubles to be rare in the course of chronic malaria. *Progrès Medical, September* 28, 1901.

Some Cases of Extragenital Syphilitic Chancres.—Leon Dervillé reports several cases in which the chancre was found on the lower lip, upper lip, tongue, or palate. He emphasizes the fact that syphilis does not always result from venereal contagion. It is sometimes contracted innocently, and this should not be lost sight of by the physician. It is at times difficult, even impossible, to determine the point of entrance of the virus. The mouth, after the anogenital region, is the most frequent seat of syphilitic chancre. Chancres of the tongue are relatively rare. Chancres of the palate are rare, few examples being found in literature. *Journal des Sciences Medicales de Lille, Sept. 28, 1901.*

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

First Semi-Annual Meeting, Held in New York City, October 15 and 16, 1901.

First Day—Tuesday, October 15.

THE meeting was called to order by the President, Dr. HENRY ELSNER of Syracuse, in the hall of the New York Academy of Medicine at 9.45 A.M.

A Contribution to the Pathogenesis of Narcolepsy and other forms of Morbid Sleepiness.—Dr. HEINRICH SIERN of New York read a paper with this title. He said that the primary factor in the causation of pathologic sleep does not arise in the brain. The term narcolepsy implied a sudden, uncontrollable inclination to sleep, occurring repeatedly, and after varying intervals. The first description of a narcoleptic attack had appeared in 1880. The latest writer, Furet, considered narcolepsy as a manifestation of autointoxication, and that it is often associated with epilepsy as evidence of one intoxication. The speaker reported a typical case. It was worthy of note that the sleeping seizures occurred independently of the ingestion of food. The patient had presented none of the minor phenomena of hysteria, and possessed an active mind. The physiological sleep at night did not refresh him. The case was reported in great detail, including analyses of the stomach contents and of the urine, the determination of the relative urinary toxicity, and examinations of the blood. The chief clinical features were: (1) A diurnally recurring morbid somnolence; (2) free perspiration on the hands, feet, and forehead at all times, and particularly before the attacks; (3) the physical conditions were uninfluenced by the attacks; (4) the heart was weak and slightly hypertrophied; (5) the stomach was dilated and hyperchlorhydria was present; (6) there was high urinary density and acidity; (7) the urinary chlorides were very largely in excess; (8) the salts of sulphuric and uric acids, carbamid, creatinin and creatin, and oxalate were found to be in excess when the urine for the twenty-four hours was examined; (9) there was diminished alkalescence of the blood; and (10) there was a low degree of relative urinary toxicity before, as well as after, the attack of somnolence. As in this case there had not been a single symptom pointing to any of the known types of autointoxication, the author concluded that the latter could be excluded as an etiological factor. He pointed out that a deficiency of chlorides in the blood gives rise to a low osmotic pressure, and that, as a consequence of the decreased osmotic tension, there results a temporary diminution in the nutrition or stimulation of the nerve substance, and, therefore, an interference with its electrical conductivity. Sudden seizures of somnolence were explicable by the lowered nerve impulses conducted through the cells of the central system. This diminution of osmotic tension was by no means identical with an anæmic condition of the central nervous system during the narcoleptic state. Neither diminished nor increased blood supply, as such, appears to exert any influence upon the production of sleep seizures; the latter appear to be due, in the first instance to diminished ionization of the chlorides in the blood.

Dr. EDWARD D. FISHER of New York said that he could recall from his experience many similar cases, so far as the symptoms were concerned, which had been dependent upon certain definite conditions. For instance, it was not uncommon to find this condition in specific cases. Frequently there was no other symptom present except this abnormal tendency to sleep, which lasts for hours or, perhaps, days. To his mind, this was almost pathognomonic of cerebral syphilis, if hysteria, diabetes, and disease of the kidney could be excluded. The underlying condition was apparently some form of endarteritis, usually endarteritis syphilitica.

Dr A. JACOBI of New York agreed with the last speaker regarding syphilitic endarteritis as an etiological factor and was inclined to think these cases were quite frequent. Sometimes the condition under discussion was ushered in by an attack of melancholia. Only that very day he had seen a case of this kind which illustrated another phase of the etiology, i. e. masturbation.

Dr. B. O. KINNEAR of Clifton Springs, N. Y., said that sleepiness was nearly always accompanied by a poor circulation in the lower part of the body and by hyperæmia of the head. If a person awakened feeling tired, it was an indication to him of the existence of cerebral hyperæmia.

The Etiology and Identification of the Cardiac Neuroses, with Special Remarks on the Nomenclature.—Dr. JAMES R. CROOK of New York read a paper with this title. It had become known to physiologists, he said, that the power of cardiac pulsations was not engendered in, or derived from, the nervous system, but rested in the musculature of the organ itself. But the supreme influence of the nervous elements in regulating and controlling the mechanism of these movements was also fully established. The vasomotor influences of the nerves of the heart had also been fairly well made out. But while the branches of biology and physiology had accomplished much in establishing the parts played by the different structures entering into the delicate machinery of the circulating centers, the knowledge thus gained had not aided as greatly in a definite appreciation of the pathogeny of the various disordered states of the heart designated as neuroses, nor had it quickened, to any considerable extent, our perception of the clinical phenomena. The nomenclature of the cardiac neuroses was at the present time in a very unsatisfactory state. There had been of late years a tendency to a multiplexion of the terms used in characterizing the nervous disturbances of the heart. Unfortunately, different writers were not fully agreed as to the use of these terms. A case, for example, that would be described by one writer as one of tachycardia, would by another be designated as neurasthenia cordis or, possibly, as irritable heart. Some of the terms recently employed represented no real symptom-group and expressed little more than symptomatic features. The reader of the paper suggested the following designations: (1) Palpitation; (2) tachycardia; (3) bradycardia; (4) the dyspeptic heart; (5) neurasthenia cordis or weak heart; (6) irritable heart; (7) arhythmia, including tremor cordis and delirium cordis; (8) the heart in Basedow's or Graves' disease; (9) angina pectoris and pseudo-angina. Of these terms, palpitation, tachycardia, neurasthenia cordis, arhythmia, and angina pectoris were essential and gave expression to diseased states, of which all writers took cognizance. The remaining titles did not express clearly defined symptom-groups, but were retained provisionally as marking regions concerning which further knowledge was required. The reader of the paper then took up in detail the various nervous disturbances, dealing especially with their causation and the marks by which they can be identified.

Dr A. ROSE of New York said that the term tachycardia, when used by itself, meant nothing. To make the diagnosis of paroxysmal tachycardia, however, required prolonged observation. This condition of the circulation was a common accompaniment of gastroptosis, and was relieved by strapping the abdomen with adhesive strips and giving its contents the needed support.

The Official Relation of the Medical Profession to Private Charitable Institutions.—Dr. ENOCH V STODDARD of Rochester, Commissioner of the State Board of Charities, presented this communication. He emphasized the seemingly trite fact that charitable institutions were established primarily for the inmates, and not the inmates made for these institutions. The special objects of the

paper were: (1) To call attention to the vast field of observation now but slightly cultivated; (2) to the fact that it was almost exclusively through the medical profession that this could be made available.

Cerebral Apoplexy.—Dr. Edward D. Fisher of New York presented this paper. He said that the term cerebral apoplexy was used by him here in the sense of any insult to the brain due to arterial causes, whether thrombosis or embolus. A most common etiological factor was atheroma of the cerebral vessels, and general atheroma with sclerosis of organs, and the common accompaniment, hypertrophy of the heart. Interstitial nephritis was usually present, and in any patient, especially one over fifty years of age, presenting cerebral symptoms of any kind, the condition of the kidneys should be carefully investigated. A persistently low specific gravity of the urine was exceedingly suspicious of slow and insidious arterial degeneration. According to his experience, the excessive periodical drinker of alcoholics was in less danger of apoplexy than the steady tippler, who is not even conscious of drinking to excess. Renal disease, the effects of alcohol, and those of syphilis constitute the three great causes of cerebral apoplexy. A most important sign of disease of the pyramidal tracts is the Babinsky reflex, *i. e.* the *extension* of the great toe on tickling the sole of the foot.

Dr. William Browning of Brooklyn said that autopsies on cases in which there had been so-called false seizures showed evidence of a number of small hemorrhages in the brain. He was of the opinion that the pain complained of in the paralyzed limb was not purely psychical, as the author seemed to think, but was often dependent upon a neuritis.

Dr. A. Jacobi of New York said that when he saw cases of complete paralysis recovering in a few hours or days, he concluded that, as a result of proliferation of the intima of certain arteries, the circulation of the part had been temporarily obstructed, and this had been quickly relieved by the establishment of a collateral circulation.

Dr. William P. Spratling of Smyrna said that he had seen in Virchow's laboratory a specimen showing that death had resulted from very minute hemorrhages in the brain.

Dr. Henry Elsner of Syracuse said that some cases of transitory paralysis were the result of a diseased endocardium and the breaking away of an embolus. Again, localized œdema in the motor area, persisting for a short time after uræmic convulsions, might give rise to transitory paralysis, sometimes hemiplegic and sometimes monoplegic.

Dr. Fisher, in closing the discussion, said that his statement about the pain in the paralyzed limb had referred to the pain complained of immediately after the attack, and before there had been time for the development of a neuritis.

The Causes and Treatment of Epilepsy.—Dr. William P. Spratling of Smyrna read this paper. He said that nearly 85 per cent. of all epileptics develop the disease before adult life, and that one in five hundred of the population is thus afflicted. Epilepsy in the parent reproduced itself in the offspring in 16 per cent. of over one thousand cases studied. Alcohol had been a family cause in 14 per cent. A powerful factor in the causation of epilepsy was infantile cerebral hemorrhage. He had known three cases of epilepsy to follow psychic shock. The epilepsies of adult life, unlike those of childhood, had no fixed etiological basis. When they were not due to delayed family causes, one would commonly find gastro-intestinal intoxication or disease of the circulatory system. Concerning the treatment employed at the Craig Colony, the speaker said that an effective plan of administering the bromides was by salting the patient's food with it in lieu of common salt. In this way, not only is bromism largely avoided, but only about one-half the usual dosage is required. A study had been made of twenty-nine cases of epilepsy that had been subjected to the operation of trephining, and the conclusion was reached that no permanent benefit had resulted.

Dr. A. Jacobi declared that a most important cause of epilepsy was asphyxia neonatorum, because even when only of a few minutes' duration, it might lead to thrombosis. If he were confronted with a post-partum hemorrhage and asphyxia of the newly born infant at the same time, he would unhesitatingly choose to direct his energy first to the child, on the ground that it was in the greater danger. Every minute of delay was fraught with great danger to the infant. Premature ossification of the cranial sutures was another important cause of epilepsy.

Dr. Carlos F. MacDonald of New York said that he was more and more inclined to look upon heredity as a powerful etiological factor, and to attribute less significance to the so-called exciting causes of the disease. In those cases exhibiting marked heredity he felt that even at the present day a cure was impossible. He believed it was absolutely useless to expect to cure epilepsy by an operation except in those cases which are traumatic, pure and simple.

Hallucinations; Their Pathogenesis, Clinical Import, and Medico-Legal Value.—Dr. J. Leonard Corning of New York read a paper with this title. After defining hallucinations, the author divided them into primary and secondary. The former, he said, were excited by irritation, while the latter were evoked by dissociative ideation processes. Among the insane the most common hallucinations were those affecting the hearing. Hallucinations of sight were exceedingly characteristic of poisoning by mineral and vegetable poisons. He protested against the habit of considering hallucinations as consistent with mental health.

Dr. C. F. MacDonald said that the hallucinations of the insane were undoubtedly of central origin, and arose in the organs in the cortex regulating sense perceptions. One evidence of this origin was the fact that insane persons who are deaf often have very active auditory hallucinations.

Dr. Edward D. Fisher took exception to the statement that the hallucinations of the insane are altogether central. The only difference between the hallucinations of the sane and of the insane was that the sane man finally recognizes that the thing is a hallucination, while the insane accept the hallucination as true.

Dr. B. O. Kinnear of Clifton Springs, N. Y., thought these hallucinations were probably the result of an excessive quantity of blood in the nerve centers.

Spinal Anæsthesia.—Dr. Willy Meyer of New York presented this paper. He said that the probable reason for the widespread objections among surgeons to the use of spinal anæsthesia was that the surgeon was not as yet master of the situation when this form of anæsthesia was used, so much depending upon individual peculiarities. Quite recently he had used spinal anæsthesia in all classes of cases and had experimented with tropo-cocaine. The advantages of the latter agent were: (1) It is less than half as toxic as cocaine; (2) that recovery from its effects is much more rapid; (3) the solution is much more stable. He was of the opinion that, at present, spinal anæsthesia should only be used under strict indications.

Dr. Herman Mynter of Buffalo said that he had had a little experience with spinal anæsthesia, but was compelled to say that it possesses certain disadvantages. One of these was graphically described by the speaker in reporting a hernia operation. The patient had been suddenly seized with persistent and explosive vomiting, and this had caused a complete evisceration of the patient. A touch of humor was given to this serious situation by the ludicrous picture of the patient raising his head and viewing his sad plight.

Therapeutics and the Drug Manufacturer.—Dr. Brace W. Loomis of Syracuse read this paper. In it he made an

earnest plea for more rational therapeutics and less dependence on ready-made formulas.

Prolonged Medication.—Dr. A. JACOBI of New York was the author of this paper. He dwelt particularly on digitalis, and said that he had been accustomed to use it in small doses for long periods at a time, and had noted nothing but good from such practice. His main reliance was on a good fluid or solid extract. Of the latter he would give ½ to ¾ gr. as a daily dose to an adult, and this he would not hesitate to continue for months. Years of cardiac ailment should be met by years of medication. Chronic myocarditis was no contraindication. He never treats chlorosis without adding digitalis to the iron.

Some Notes on the Early Diagnosis and Treatment of Pulmonary Tuberculosis.—Dr. J. ELWOOD STUBBERT of Liberty presented this paper. Commenting upon the necessity for an early diagnosis, he said that out of 100 incipient cases, taken at random from the case-books of the Loomis Sanitarium, 51 per cent. had been cured and 12 per cent. arrested, or a total of 63 per cent. of practical cures; whereas out of 100 moderately advanced cases, taken in the same way, only 2 per cent. had been cured and in 7 per cent. the disease had been arrested—in other words, treatment of the incipient cases yields 63 per cent. of successes as contrasted with 12 per cent. among moderately advanced cases. Gradual loss in weight and increased activity of the heart's action should always lead to an examination of the chest. In his experience, inspection of the chest posteriorly had often given more information than an examination of the anterior regions. Very little reliance could be placed on deficient expansion of the chest, as determined by inspection and palpation. Among the early physical signs were a high-pitched percussion note in the infraclavicular region, slightly increased vocal resonance, and prolonged high-pitched expiration and bronchovesicular rather than bronchial breathing. Cogwheel respiration was not, as a rule, observed in the early stage. A faint râle or a single sticky sound might sometimes be made out after coughing. It should not be forgotten that the absence of bacilli in the sputa was not sufficient to exclude diagnosis of pulmonary tuberculosis. Tuberculin had not fulfilled our expectations, because a tuberculin reaction had been obtained in a certain proportion of cases of syphilis in all stages, and there had been no reaction in a number of cases of tuberculosis. Researches carried on at the laboratory of the Loomis Sanitarium seemed to show that pure tuberculosis has but little effect on the blood, and that the primary cause of the anæmia is the presence of the diplococcus lanceolatus along with the tubercle bacilli. The slight rise of temperature occurring in pure tuberculosis has no effect on the hæmoglobin. The temperature in the cases of mixed infection deprives the red corpuscles of their vitality and diminishes their number. The blood effused in pulmonary hemorrhage does not show any nucleated red cells. These facts show that examination of the blood of tuberculous individuals is not of much value. The fluoroscope and the Röntgen rays enable one to ascertain with a considerable degree of accuracy the position and relation of the areas of consolidation. In about 50 per cent. of the cases the right apex is not quite so clear as the left. A slight shadow is cast by the deltoid muscle. Where there is only a very slight infiltration, the Röntgen rays reveal a haziness around the clavicle or at its edges. Concerning the question of treatment, Dr. Stubbert declared that he did not believe even incipient cases could be effectively managed by climatic treatment alone, and he considered a patient suffering from pulmonary tuberculosis better off at home under medical care than at any health resort without medical supervision and treatment. He made it a rule to examine the pharynx and larynx in every case at the first visit, and at once to institute appropriate treatment. The anæmia of early cases was effectively combated by high altitude and an outdoor life, supplemented by the administration of iron and arsenic, and the use of static electricity and hydrotherapy. Antituberele serum was apparently useful in some cases through its action in improving the phagocytic power of the blood. Dr. Stubbert's paper was supplemented by a lantern exhibition of Röntgen-ray photographs from patients in various stages of pulmonary tuberculosis.

The Association of Pulmonary Tuberculosis with Both Primary and Secondary Endocarditis, and the Effect of Valvular Disease upon Lung Tuberculosis.—Dr. J. M. ANDERS of Philadelphia, Pa., presented this communication. He said that cases of endocarditis due to the tubercle bacillus were decidedly rare. When it did occur, it was probable that the infection took place through the blood supply of the heart itself, and not from the blood circulating in the organ. Tuberculosis of the pericardium is more frequent. In most cases of valvular disease of the heart, presenting pulmonary tuberculosis as a complication, the latter usually passed unrecognized during life. The paper embraced a broad statistical study of the subject. The author stated that medical authorities agreed that chronic valvulitis exerted a distinct retarding effect on pulmonary tuberculosis. The mistake was often made of sending such cases to resorts having a greater altitude than 2,000 feet. Statistics seem to prove that stenosis of the pulmonary artery predisposes to pulmonary tuberculosis.

Dr. HENRY L. ELSNER of Syracuse says that he had found out of 214 cases of pulmonary tuberculosis only 10 presenting heart murmurs. The majority of these cardiac cases had presented the murmur of mitral insufficiency. A case was mentioned in which there had been associated tuberculous myocarditis and nodules with tuberculous endocarditis. He had also seen a case in which there had been a tuberculous deposit in the shape of a polypus over the pulmonary artery. There had been no evidence of endocarditis during life.

Muscular Atony an Important Factor in Uterine Displacements.—Dr. H. C. COE of New York read a very suggestive paper with this title, in which he contended that uterine displacements are largely dependent on a lack of tone of the muscles of the abdomen, pelvic floor, and vagina. The fact that some women who had borne children do not experience any difficulty until after the menopause, when the uterus had become atrophied, tended to confirm this view. Evidently, one should not rest content with mere plastic operations.

Dr. EGBERT H. GRANDIN of New York said that the symptomatology of uterine displacements was dependent upon the degree of descent of the uterus, and the consequent impairment of the pelvic circulation; therefore a cure could not be effected unless, in addition to repairing lesions of the cervix and pelvic floor and the use of measures directed toward improving the general muscular tone, one of the suspensory operations were done—either Alexander's operation or the operation of suspensio uteri.

Abdominal Actinomycosis, with Illustrations and Report of a Case.—Drs. ALBERT VAN DER VEER and ARTHUR W. ELTING of Albany presented this paper. They stated that the disease actinomycosis could no longer be considered a rare affection. The great source of actinomycotic infection in man was vegetables, especially cereals. The chief avenues of infection were (1) the mouth and pharynx; (2) the respiratory tract, (3) the gastro-intestinal tract. The blood vessels in the immediate vicinity of a focus were rarely obliterated. There were two great types of infection: (1) the neoplastic, usually found in horses and cattle, (2) the inflammatory type, usually found in man. Abscess cavities were usually the result of secondary infection. The disease process tends to extend by continuity rather than by metastasis. In the

majority of cases the metastasis takes place through the veins. Abdominal actinomycosis was divided into three periods: (1) The initial period; (2) the period of tumor formation; (3) the period of fistulæ. Pain was rarely severe. The duration varies from a few weeks to several years. The prognosis was not necessarily hopeless.

Mechanical and Operative Treatment of Hip Disease and Disease of the Spinal Vertebræ.—Dr. A. M. PHELPS of New York, instead of reading a paper, demonstrated a few of the more important points connected with the treatment of these cases.

Dr. W. R. TOWNSEND of New York, in discussing the subject, said that while theoretically lateral traction was proper, many surgeons had not yet been convinced that Dr. Phelps had ever succeeded in making lateral traction. He would agree with the statement that there was no need for cases of hip-joint disease to end in angular deformity and ankylosis.

The Advantages of Stereoscopic Radiography.—Dr. LOUIS A. WEIGEL of Rochester read this paper. The apparatus for the production of stereoscopic radiography was demonstrated, and numerous plates were exhibited.

Dr. CARL BECK of New York exhibited several patients and *x*-ray pictures of the same.

Symposium: Some Diseases of the Liver and Bile Passages; the Diagnosis of Gall-Stones and Their Aberrances.—Dr. CHARLES G. STOCKTON of Buffalo opened the symposium with this paper. He said that recent research had demonstrated that preceding every cholelithiasis there was an infection of the gall-bladder. This is later encapsulated and salts deposited, thus giving rise to gall-stones. In a large series of autopsies in females over seventy years of age, 25 per cent. showed gall-stones. Seven varieties of cholelithiasis were described. These were dependent upon adhesions of the gall-bladder, adhesions of the stone, and patulousness of the duct. A stone in the ductus choledochus was not always followed by jaundice. There might be fever lasting for a week or more, and yet pus might not be present. Albumin and casts were generally present in the urine in acute cholecystitis; they were never absent when jaundice was persistent. In simple empyema of the gall-bladder, there was very often absence of fever. One or more of the following symptoms were always present in cholelithiasis: Paroxysmal pain and tenderness at the junction of the ninth costal cartilage, vomiting, rigors, fever, tumor, jaundice, and calculi in the stools.

Courvoisier's Law.—Dr. RICHARD C. CABOT of Boston, Mass., took up this subject. He said that this law had been formulated by Courvoisier in 1890, but it was not generally known to the profession. He analyzed a large series of cases, and concluded that, when the common bile duct is obstructed by stone, the gall-bladder does not enlarge, whereas, when obstructed from other causes, enlargement is generally present. The author had examined the histories of eighty-six cases of gall-stone obstruction occurring in the Massachusetts General Hospital. Of this number, fifty-seven had been due to obstruction by gall-stones; in only two cases was the gall-bladder enlarged. In twenty-nine cases was the obstruction due to other causes than stone, and in only two of these was there no enlargement. The explanation offered of this seemingly anomalous fact was that, when there is a stone in the common duct, there were generally also one or more stones in the bladder itself, and the irritation caused by these stones results in inflammation of the bladder, and consequently in contraction of the bladder. This law, this speaker said, was of great value in separating operative from non-operative cases of chronic jaundice with or without enlargement of the gall-bladder.

The Infections of the Gall Bladder and Bile Ducts.—Dr. B. FARQUHAR CURTIS of New York discussed this subject. He said that normal bile, contrary to former opinion, is now believed to have no germicidal influence. The normal bladder contained, in a large percentage of cases examined, many forms of microorganisms, including the streptococcus and staphylococcus. These bacteria are carried there from the intestine and also by the blood. Cholecystitis might be due to obstruction from flexure of the duct, stricture of the duct, stone, and traumatism. Gangrene of the gall-bladder was rare; when it did occur, it it was usually present at the fundus. The prognosis of cholecystitis was much graver than had hitherto been supposed. In the diagnosis of cholecystitis few mistakes would be made if one ascertained the relation of the seat of pain to the liver and not to any fixed point in the abdomen. Leucocytosis was an unreliable sign of pus in cases of empyema of the gall-bladder. Many cases of diaphragmatic pleurisy refer the pain to the region of the gall-bladder. This could be differentiated by the different character of the respiration in the two classes of cases.

Intestinal Obstruction Due to Gall-Stones.—Dr. L. S. PILCHER of Brooklyn took up this topic. He stated that this was a comparatively rare form of intestinal obstruction. In 1,000 cases of intestinal obstruction, forty were due to gall-stone. It generally occurred in women over fifty. It was not so much the bulk of the stone that gave rise to the obstruction as the secondary conditions which develop along the course of the bowel, such as angulation and local peritonitis. Gall-stones do not generally cause any trouble until the lower part of the small intestine is reached. Generally, fecal vomiting comes on very early. Shock and pain are comparatively slight. In 50 per cent., the gall-stone passes without operation. Cancer of the small intestine and internal hernia may cause the same symptoms, and for that reason exploratory section was advisable early in all cases presenting these symptoms.

Technique of Gall-Bladder and Duct Operations.—Dr. S. J. MIXTER of Boston, Mass., presented this paper. He said that in surgery of the gall-bladder rubber gloves should not be worn. In palpating the gall-bladder it was advisable to pass the left forefinger through the foramen of Winslow, with the operator's back turned towards the patient's face. All cases of gall-bladder surgery should be drained. If there was no need for drainage the wound would close in a few days; if the wound does not close, then to have closed that wound would have meant the death of the patient. A glass tube with a flaring end should be fastened into the gall-bladder by means of a strong suture. A rubber tube is attached to this, and the bile drained into a vessel under the bed. In a few days the suture would cut through and come away. Cases in which the common duct had been opened did equally well whether sutured or not. Oozing surfaces were often very difficult to treat. Gelatin and adrenalin were suggested as useful in this connection.

Cholecystectomy.—Dr. C. L. GIBSON of New York read this paper. He said that cholecystectomy was the only absolutely curative operation in disease of the gall-bladder, for the reason that it completely removed the cause of the disease. It was also advisable as a prophylactic measure against malignant disease, inasmuch as 14 per cent. of cases of cholelithiasis were followed by malignant disease. The mortality from this operation was about 3 per cent. It was advisable in all cases of gall-bladder disease when it could be done easily. In cases of cholecystotomy where drainage was employed the gall-bladder was always obliterated.

Syphilis of the Liver.—Dr. SIMON FLEXNER of Philadelphia, Pa., was the author of this paper. He said that gummata were generally present on the surface of the liver under the peritoneum. There were three forms of syphilitic disease of the liver, viz.: Simple, interstitial, and gummatous hepatitis. To these might be added amyloid degeneration. There had been no important improvement on Virchow's original classification. In

5,088 autopsies done at the Philadelphia Hospital there were 88 cases of syphilis of the liver. Of this number, 46 had interstitial hepatitis, 33 perihepatitis with gumma, and 7 had amyloid degeneration. In simple gummatous hepatitis ascites not appear. Contrary to the general opinion formerly held, amyloid change might be resorbed under treatment.

Tumors of the Liver.—Dr. G. R. FOWLER of Brooklyn discussed this topic. He said that carcinoma was the most common form of tumor in the liver. In most cases it was secondary to growth in the stomach. The echinococcus was the next most frequent. Jaundice was not a necessary accompaniment of echinococcus cysts. The fluid from these cysts, in addition to hooklets, contains succinic acid. The cyst should be excised, and at the same time a small piece of the liver, to which the cyst is adherent, should be cut off and the base cauterized with the actual cautery. Five such cases had been treated in this way by the author with successful result. Simple cysts contain no hooklets, but do have albumin, and this serves to differentiate them from echinococcus cysts. Multilocular disease was generally associated with the same disease of the kidney. It was very rare, and was of no importance. Other tumors were comparatively rare. In floating liver, the organ should be sutured to the diaphragm and also to the right rectus muscle.

Dr. J. D. BRYANT of New York in describing the functions of the gall-bladder, called attention to the fact that those animals which feed on starchy food have very little need of the gall-bladder, whereas those whose diet consisted of proteids entirely could scarcely live without it. If difficulty were experienced in reaching the liver because of a very deep chest or high position of the organ, it could be easily brought forward by passing the hand backward between the liver and the diaphragm and pressing forward.

Dr. R. H. M. DAWBARN of New York called attention to Mayo's plan of needling the gall-stone when it is in the duct and cannot be easily reached from the intestine. Another point suggested by Mayo was that, when the duct was opened and drainage employed, the gauze should be sutured with the same sutures used to close the duct. This keeps the gauze in place.

Second Day—Wednesday, October 16.

Medical Aspects of Appendicitis.—Dr. W. E. LORD of Utica presented this paper. He said that statistics seem to show that athletic young people were more apt to have appendicitis than others. It was not probable that this was because of the action of the psoas muscle, but rather because this class of persons was apt to eat coarse, hearty food and to devour their meals hurriedly. He doubted if traumatism had much to do with the causation of appendicitis. Habitual constipation, over-distention of the bowel with unwholesome or partly digested food, and violent exercise immediately after meals were important factors in the etiology. During the first twenty-four hours an ice coil may be kept on the abdomen. The chief points in the diagnosis were the presence of rigidity of the right rectus muscle and a feeling of bogginess in the region of the appendix. If the pulse and temperature returned to the normal and the bowels moved freely in twenty-four hours, it was safe to wait before considering the question of operation. Pain in the appendix is usually paroxysmal. If, after thirty-six hours of such pain, not relieved by the ice coil and cathartics, the pain suddenly ceased there was strong probability that perforation had occurred, and immediate operation was, therefore, indicated. No one symptom was sufficient for the diagnosis. Careful palpation of the abdomen and a proper appreciation of the physical signs were the only just grounds for operation. There should be no difference of opinion between the medical and surgical households if the diagnosis of the fulminating type could be made out, and this, he thought, could be done, and by the medical man. Operation should certainly be done in those cases in which the physical signs of appendicitis persist, if only because of the danger of prolonged sepsis. Persistent vomiting and pain in the abdomen did not seem in themselves sufficient to justify a diagnosis of appendicitis.

Dr. HERMAN MYNTER of Buffalo, in discussing the paper, said that the appendix possesses a low vitality and has only one artery, the circulation in which is readily cut off. It was an organ which very easily becomes inflamed, and statistics showed that this inflammation was very prone to recur again and again. He was of the opinion that every moderate attack of appendicitis is associated with such serious changes that relapse is almost certain. Our knowledge of the pathology of appendicitis had taught us that every case of this disorder begins as a catarrhal inflammation, and that this is soon followed by stricture, thus affording an opportunity for bacterial invasion with all its disastrous results. The speaker then attacked the statistics often brought forward in favor of the medical treatment of this disorder, and declared that the 80 per cent. supposed to recover under medical treatment were the cases that would have recovered without any treatment. Relapses occur in 50 per cent. of the cases, and the mortality is really 05 to 75 per cent.

Dr. ROBERT T. MORRIS of New York said that the term "catarrhal appendicitis" had exerted almost as fatal an influence as the expression "gonorrhœal rheumatism." While he believed that every case begins as a catarrhal appendicitis, it was doubtful if there were any symptoms present during the catarrhal stage.

Dr. JAMES NEIL of New York reported a case in support of his belief that even severe cases of appendicitis, not merely catarrhal ones, were sometimes amenable to medical treatment.

Dr. BARSTOW said that his studies in pathology had convinced him that appendicitis is essentially an inflammation associated with a bacterial infection, and hence he could not resist the conclusion that such cases should be treated surgically.

Dr. WHITEFIELD said that the bacteriology of appendicitis was not uniform, and he was inclined to believe that in chemical pathology would be found the true etiology of this disease. In a study of this subject he had found an excess of organic acids in the cæcum and about the orifice of the appendix. This suggested that in the early stage of appendicitis at least, treatment directed toward reducing the acidity of the intestinal canal was appropriate.

Dr. LORD in closing the discussion said that the only object of his paper was to call attention to certain medical facts which should be carefully formulated and well understood. The medical man should have well-defined ideas as to what he should do before it is advisable to call a surgeon to his aid.

The Etiologic Potency of Heredity in Mental Diseases.—Dr. CARLOS F. MACDONALD of New York presented this paper. He said that heredity manifested itself in this field chiefly in three ways, viz.: (1) Congenital absence of the mind; (2) arrest of development in early life before the mind had fully developed, and (3) development of a psycho-neurotic temperament or insane diathesis, as shown by an unstable nervous organization, which makes its possessor become easily the victim of circumstances. Insanity rarely occurs in individuals who are not predisposed thereto, but all so predisposed persons did not, by any means, develop insanity. The explanation of this was to be found in the neutralizing effect of one parent, in an insufficient exposure to exciting causes, or through the intervention of the law of variation, which renders the action of inheritance uncertain.

Dr. WILLIAM MABON of Ogdensburg said that, while undoubtedly a small proportion of cases of insanity originate in heredity *per se*, it was equally true that

the indirect influence of heredity is felt in a very large proportion, probably in from 85 to 95 per cent. Many cases of hereditary insanity break down in the physiological crises of life, *i. e.* at the age of puberty and at the climacteric. A curious effect of heredity was the transmission of the same form of mental disease through several generations. Out of four hundred and thirty-two admission to the St. Lawrence State Hospital for the Insane during one year, one hundred and fifty-five, or 36 per cent., presented a distinct history of heredity. Of these one hundred and fifty-five, the transmission had been from the paternal side in fifty-seven, from the mother in sixty-four, and from both father and mother in fifteen, while twenty-three had a collateral inheritance. Nothing could be ascertained regarding heredity in 31 per cent.

Dr. EDWARD D. FISHER of New York did not think heredity bore any closer relation to mental than to many other diseases. According to his experience general paralysis of the insane is not hereditary, and the explanation was to be found in the fact that this is essentially an acquired disease, being due not to inherited, but to acquired, syphilis.

Dr. MACDONALD in closing said that he had not intended to imply that paresis or any other form of insanity is inherited, but rather that persons, who are not predisposed to mental or nervous disease by reason of inheritance, seldom break down from the so-called exciting causes of paresis.

The Pathology and Treatment of Migraine.—Dr. WILLIAM H. THOMSON of New York presented this paper. He pointed out that migraine could not be ranked among the class of nervous diseases called degenerative. It was a significant fact that outdoor workers are almost without exception exempt from this malady, while persons living indoors and leading sedentary lives, as for example, professional men and brain-workers generally, were notorious sufferers from migraine. The habits of life of this class of persons are such as affect the portal circulation, and this formed the fundamental fact in connection with what he termed "the autotoxic treatment" of migraine. To secure an antiseptic effect on the bowel, he made use of mercurial cathartics and saline laxatives. All persons, without exception, who suffer from severe migraine are chronic dyspeptics, and are habitually constipated. The author recommended that from 1 to 2 dr. of sodium sulphate and 10 gr. of salicylate of sodium be dissolved in a tumbler of hot water and slowly sipped in the morning on arising. Some prefer the phosphate of sodium, but he did not consider it so efficient. Half an hour before meals he gives $\frac{1}{10}$ gr. of bicarbonate of potassium with 3 gr. of bismuth subcarbonate, and half an hour after meals full doses of intestinal antiseptics—10 gr. of naphthol or phenol bismuth and 10 gr. of sodium benzoate, in 2 capsules. For the treatment of a severe attack of migraine he knew of nothing better than drachm doses of the fluid extract of ergot, given in the elixir of cinchona either by stomach or rectum. The patient must be kept absolutely quiet. To combat the agonizing pain, one may prescribe 15 gr. of antipyrin always with a drachm of the aromatic spirits of ammonia. A proper dietary was most important, and the most generally serviceable rule in this connection was that whenever any article of the diet, whether fluid or solid, "repeats," that article must be excluded from the dietary. As migraine sufferers were always made worse by worry or mental strain, they should lead a very quiet life.

Dr. A. JACOBI of New York said that it was most important in these cases to combat the associated cerebral anæmia. For many years he had relied upon aconitia and cannabis indica in the treatment of the attack, but it should be remembered that only disappointment was to be expected unless the physician took the precaution to prescribe *Duboisia* or aconitia or the *extract* cannabis indica. The latter preparation should not be given in doses larger than ½ to ¾ gr. a day. In many cases he added small doses of strychnia or arsenic.

A Case of Non-Traumatic Perinephritic Hemorrhage.—Dr. ARTHUR BOOTH of Elmira reported this case. The subject of it was a man, thirty-eight years of age, having an excellent family history. He had indulged rather freely in alcohol for many years. The occurrence of the hemorrhage was announced by sudden pain in the region of the kidney associated with severe collapse. Physical examination showed a mass of undetermined nature in the flank. The diagnosis was not made during life. There seemed to be no good reason for the occurrence of this hemorrhage unless it might be alcoholism and the consequent atheroma. The case was reported because of the extreme rarity of spontaneous hemorrhages of this kind.

The Technics of Nephropexy, as an Operation per se, and as Modified by Combination with Lumbar Appendicectomy and Lumbar Exploration of the Bile Passages.—Dr. GEORGE M. EDEBOHLS of New York presented this paper. He said that the frequent coexistence of movable right kidney and chronic appendicitis often call for nephropexy and appendicectomy upon the same patient. These operations, when necessary, should both be performed at one sitting through one and the same lumbar incision, as was first proposed, and has now been done fifty-three times by the author. The frequent association of disease of the gall bladder and bile ducts with movable right kidney rendered it very desirable to know the exact condition of the biliary apparatus of every patient operated upon for fixation of the right kidney, provided that such knowledge could be gained without added risk to the patient.

When in the performance of right nephropexy, therefore, the peritoneum was opened for the removal of the diseased vermiform appendix, it was the frequent practice of the writer to take advantage of the existing peritoneal opening for thorough exploration of the gall bladder and bile ducts by palpation, and, if necessary, by direct inspection.

This exploration of the biliary passages could be accomplished through a properly placed right nephropexy incision as readily as through an anterior abdominal incision of equal extent. Nephropexy, therefore, as now practised by the writer, included, in the majority of his operations, simultaneous lumbar appendicectomy, and in a number of them lumbar exploration of the biliary passages. The history and literature of nephropexy were given in full detail, and the various methods of anchoring the kidney critically reviewed. The writer said that up to about a year ago he had advocated and practised fixation of the denuded kidney to the rawed quadratus lumborum by sutures piercing both the capsule proper and the parenchyma of the kidney. While retaining the other features of his former method, he had abandoned the use of sutures through the kidney substance, being influenced in this action partly by the researches of M. Wolff, which prove conclusively that destruction or loss of renal tissue is compensated for by hypertrophy of the remaining elements, but never made good by new formation of tubules and glomeruli. Questions of practical technics, however, relating to fracture of the kidney by sutures, leading, in three cases collected from the literature and in one of the writer's own cases, to urinary fistula, had clinched the decision.

His present technics include entire removal of the fatty capsule, incision of the capsule proper over the convexity of the kidney from pole to pole; reflection of the capsule proper on either side to about the middle of the anterior and posterior faces of the kidney, laying bare the kidney substance over about half the surface of the organ; resection of the reflected capsule proper if too excessive; suturing apposition of the denuded kidney to the rawed

quadratus lumborum; and retention of the organ in this position by four buried sutures of forty-day catgut, passed through both the reflected and the still attached capsule proper without penetration of the kidney substance. The skin is closed for primary union without drainage. The collected statistics of fifteen operators, each of whom had performed nephropexy fifteen times or more, gave 823 operations with 14 deaths, or a mortality of 1·7 per cent. His own operations numbered 103, of which 125 were unilateral, and 68 bilateral nephropexies, making a total of 261 kidneys fastened. Of the 103 patients three had died as the result of the operation, making the writer's mortality 1.55 per cent. The great proportion of bilateral nephropexies, and the large number of additional operations (appendicectomy in 53 cases, and nephrectomy in 2, amongst others), performed by the writer at the same sitting with nephropexy, should be taken into account in judging this mortality. The results, as far as regards permanent anchorage of the kidney, had been most gratifying. The large majority of his patients had been repeatedly examined by him, very many of them years after operation, and in no instance had the anchored kidney been found again detached. Two detachments only had been reported to him by other physicians, but the opportunity to verify or disprove their diagnosis by personal examination had not been afforded the writer. The therapeutic results of nephropexy were satisfactory in proportion to the knowledge and judgment displayed in establishing the indications for operation. They depended, also, in quite a number of cases upon the successful removal of other conditions producing symptoms in the same patient. Properly applied in properly selected cases, nephropexy was one of our most potent means for the relief of human suffering.

Morcellement and Bisection of the Uterus in Complicated Abdominal Hysterectomy.—Dr. W. G. Macdonald of Albany described, with the aid of a series of drawings, the technique employed by him in this operation.

Dr. Howard A. Kelly of Baltimore, said he was glad that a paper he had written recently on this subject had inspired Dr. Macdonald to do such good work. The technique described had been devised in order to lessen the difficulty often experienced in getting at the adnexa.

Method of Incising, Searching and Suturing the Kidney for Stone.—Dr. Howard A. Kelly of Baltimore briefly described this method. The main points involved had been worked out by his artist, Mr. Broedel. Among other things, this gentleman had rediscovered an old and long-forgotten anatomical fact, *i. e.* that the vascular supply of the kidney is absolutely divided into two portions between which there is no communication. The major part runs over the anterior face, while the posterior third is supplied by a single branch. It was evident that if one could cut between these two, there would be no hemorrhage. Mr. Broedel had discovered that a white line found on the surface of the kidney, near the dorsum, and extending its length, shows the most vascular part. An incision into the kidney should, therefore, be made posterior to this line and through the center of the lobules, taking care to make this cut parallel to the posterior surface of the kidney. In this way the knife strikes the posterior papillæ. The papillæ is located by first introducing a renal catheter, and, after exposing the kidney, distending the organ with fluid. A long, straight, blunt-pointed needle, triangular in shape, is used to transfix the kidney between the papillæ. The needle is brought out at the margin of the vascular columns, and is reentered, thus making a mattress suture. By using several of these catgut sutures, one could perfectly control the circulation of the kidney without causing any injury to the kidney.

A Smallpox Epidemic in an Orphanage.—Drs. F. C. Curtis and H. L. K. Shaw of Albany reported this epidemic. They stated that it would have been difficult to make the diagnosis from the lesions alone. The epidemic was unusually mild. All the children were vaccinated during their illness with vaccine yielding 99 per cent. of successful vaccinations. Only one of the forty-five children in the institution had been vaccinated previously, and that child was the only one that failed to contract the disease.

Immediate Repair of Injuries of Parturition.—Dr. A. L. Beahan of Canandaigua read this paper. He prefers silkworm-gut and shotted sutures. The immediate repair of lacerations of the cervix, he thought, should be popularized just as much as repair of the perineum. He was of the opinion that lacerations of both the cervix and the perineum could be as successfully repaired after the lapse of twenty-four hours as immediately after parturition. The silkworm suture never fails, but to insure a good result it was essential that a considerable portion of tissue be included in the grasp of the suture.

Dr. Charles D. Jewett of Brooklyn said that general opinion was against the immediate repair of cervical lacerations, and, to his mind, this was the correct view, because of the great danger of infection after this operation. He would suture the cervix at the close of labor only when it was necessary for the control of hemorrhage. Lacerations of the perineum might be sutured at any time, he had done it successfully even ten days of more after confinement. The surfaces should be vivified by rubbing with gauze, but there was a fair prospect of good union even if this precaution were not taken. There were some advantages connected with this late repair, as, for example, the absence of hemorrhage and the ease with which the relations of the parts can be made out. He had seen more than one death because of the attempt to repair the perineum when the woman was already greatly exhausted. The levator ani muscle consists of bundles of fibers, none of which cross the median line. The tear extends up into one or both vaginal sulci. The external tear has little or nothing to do with the strength of the pelvic floor. The speaker favored the use of chromic catgut, because it holds as long as required, and does not require removal.

Dr. M. C. Potter of Rochester said that she had found late suture of the cervix difficult, though successful. More recently she had been using, with much satisfaction, the plan of waiting twenty-four hours, and then doing the operation after giving a hot intrauterine douche. It was important that the laity should be educated up to the point of expecting and desiring these reparative operations after labor.

Dr. Beahan, in closing the discussion, said that there was no more danger of sepsis from the cervix than from the perineum; hence he could not see the force of Dr. Jewett's objection. The results were just as satisfactory from immediate repair of the cervix as of the perineum, and the danger of sepsis was, by such practice, diminished—not increased.

The Present Status of Ophthalmic Science and Art.—Dr. D. B. St. John Roosa of New York presented in this communication an interesting and instructive historical sketch of the progress of ophthalmology from the time of Helmholtz.

Are the Faucial Tonsils to be Regarded as One of the Normal Organs of the Body?—Dr. F. H. Bosworth of New York propounded this question as the theme of his communication, and answered the query in the negative though not insisting strenuously on the absolute correctness of this view. Twenty years ago he had declared his belief that the faucial tonsils are not found in a perfectly healthy throat, and he was disposed still to cling to this view. He was inclined to think that partial excisions of these tonsils leave the throat in a worse condition than before; they should be thoroughly extirpated, for they constitute a constant menace to health. He had long ago discarded the tonsillar guillotine, using

in its stead the cold wire snare fitted with No. 8 piano-wire. One advantage of this method was that it makes the operation practically bloodless. In operating upon the tonsils in children under ten years of age he was accustomed to give them sufficient chloroform to prevent pain but not produce deep narcosis. Although this had been his practice for ten years or more he had yet to see any unpleasant symptoms attributable to the chloroform.

Dr. ROBERT C. MYLES of New York said that he did not know of any instance in which he had succeeded in removing all of the basic portions of the tonsils. Much of the confusion surrounding this subject arose from the absence of any definite conception of what constitutes the normal tonsil. He would describe a normal tonsil as being 20 to 25 mm. in its vertical diameter, 8 to 12 mm. in its greatest antero-posterior diameter and almost 2 to 4 mm. in its greatest lateral diameter.

Observations on the Treatment of Croupous Pneumonia.—Dr. J. C. WILSON of Philadelphia, Pa., was the author of this paper. After a careful study of available statistics, the author concludes that 75 per cent. of patients of all ages in hospitals recover, while the mortality rate is lower in healthy young subjects such as are found in military hospitals. In exceptional series of cases the mortality was only 1 to 2 per cent. Concerning the so-called specific treatment, the speaker pointed out that it was not reasonable to expect curative effects from a number of drugs selected because of their supposed action upon the cause of the pneumonia. In such infection as malaria, syphilis and diphtheria, it should be remembered that only one plan of medication is successful. Again, it was highly probable that at the time of the initial chill the disease process was already far advanced. Dr. Wilson said that his own plan was to apply one or two ice bags to the affected side, sponge the body night and morning with tepid water and administer calomel two or three times in the first week. Expectorants were rarely used, though sometimes aromatic spirits of ammonia or the carbonate of ammonia was prescribed. Alcohol was generally given, though except in alcoholic subjects only from four to six ounces of whiskey are given in the twenty-four hours. Great stress was laid upon the use of Dover's powder, two or three grains at a dose, repeated at intervals of two or three hours during the greater part of the illness. The object was to give enough of this drug to produce slight continuous drowsiness. Where a heart stimulant was indicated, strychnia was used, with nitroglycerine at times to relieve the right side of the heart. Dyspnœa was considered an indication for the use of oxygen, care being taken to dilute it largely with air. The hypodermic use of atropin was valued highly in the treatment of pulmonary œdema. Delirium and a tendency to coma are treated by cold effusions to the head and neck at intervals of a few hours. Neither poultices nor cotton jackets are allowed. The patient wears loosely fitting merino underwear. Blisters are sometimes used in cases in which resolution is delayed.

Dr. S. B. WARD of Albany said that he had almost uniformly observed unfortunate results where ice had been used in pneumonia. Tepid baths were undoubtedly beneficial, and were also grateful to the patient. His results had been better since beginning the use of such antiseptics as creosotal, but they were never continued if they interfered with digestion. The patient should be allowed to drink freely, but food should be given sparingly.

Dr. JOHN HUNTER of Toronto was invited to speak. He called attention to the value of the open air treatment of pneumonia and other respiratory diseases, and referred to his experience with this method in hospital practice in Toronto. Here, these cases are treated in tents upon the hospital grounds. The speaker declared that if he were stricken down with pneumonia, he would rather be treated in a tent in one of the parks than in the finest house in the city.

Dr. WILSON, in closing, said that what had been said by the last speaker reminded him of the better results obtained in the treatment of pneumonia in military practice and in lumber camps.

The Early Diagnosis and Treatment of Acute Mastoiditis.—Dr. T. H. HALSTED of Syracuse read this paper. He pointed out the ravages made by streptococci or influenza bacilli. The latter infection was peculiarly severe and destructive when it attacks the mastoid. Ice should be used only in the early stage, and if used properly would often make operation unnecessary. He had found cold superior to hot applications. Where there was evidence of accumulation in the middle ear, the drum should be freely incised. The canal should be kept clean by syringing; the common practice of insufflating powders was as unsurgical as it was dangerous.

Dr. J. E. SHEPPARD of New York spoke of the manner of eliciting that very important symptom in mastoid tenderness. The pressure made over the mastoid should be firm; sometimes it was desirable, by way of comparison, to make pressure simultaneously over both mastoids. Bulging of the posterior wall of the canal was so significant that he would almost be willing to make the diagnosis of mastoiditis upon this alone. According to his experience, this sign had appeared quite late.

A Case of Cerebral Abscess Complicating Chronic Otitis Media.—Dr. ROBERT LEWIS, Jr., of New York reported this case, and presented the patient, who served as an excellent object lesson of the danger of neglecting to efficiently treat a chronic otitis media.

Some Conditions Antecedent to Cancer of the Breast.—Dr. B. FARQUHAR CURTIS of New York read a paper with this title. He described the conditions present in chronic mastitis, and stated that many of these cases terminate in carcinoma. Where the induration was moderate, and few cysts were present, there was less danger of carcinoma. In these cases it was not safe to draw too fine distinctions; a portion or all of the breast should be removed depending upon the extent of involvement.

Ligation of Abdominal Aorta for Aneurism.—Dr. ROBERT T. MORRIS of New York reported this case and presented the specimen. This is the fourteenth case of the kind on record, and all had terminated fatally. Ten of the cases had occurred before the days of aseptic surgery. His patient was a feeble syphilitic woman, twenty-four years of age, who had been suffering from the aneurism for four months. He had applied a temporary ligature to the abdominal aorta, two inches below the aneurism, the intention being to cure the aneurism and then restore the circulation by removing the ligature. The ligature employed consisted of a broad soft catheter held in place by steel forceps. The aneurism was cured and the ligature was removed on the twenty-seventh day. Just as there was an excellent prospect of achieving success, the patient was unexpectedly overwhelmed by sepsis. The autopsy showed that death had resulted from gangrene of a loop of bowel brought about by the pressure of the intestine against the steel forceps. The use of the forceps was evidently a fault in the technique.

Dr. A. T. BRISTOWE of Brooklyn called attention to the fact that the larger the vessel the greater the danger of hemorrhage, the hydrostatic pressure increasing rapidly with the area. He thought it possible that the aorta might be successfully sutured. In the pre-antiseptic days a few cases of abdominal aneurism had been cured by pressure on the abdominal aorta.

A Case of Intermittent Claudication Terminating in Gangrene.—Dr. I. H. LEVY of Syracuse reported this case. He said that this condition which had been first described by Charcot, is characterized by the occurrence of cramps in one or both extremities. They are in-

duced by walking and disappear with rest. They are usually localized in the calves. Obstruction to the circulation seemed to be the chief anatomical lesion. The absence of pulsation in the arteries of the affected extremity is a constant symptom.

Dr. HENRY ELSNER of Syracuse said that the report of this case reminded him of the cases of erythromelalgia that he had reported. In those cases, it seemed pretty clear that the arteries were more at fault than the nerves.

The Beneficial Effect on the Eyes from the Use of the Stereoscope.—Dr. A. EDWARD DAVIS of New York read this paper and exhibited the stereoscope devised by Dr. Derby of New York. The stereoscope was most useful in the treatment of squint. It was essential that the distance between the eyepieces should closely correspond with the distance between the pupillary centers. The angle of the eyepieces should be adjustable.

Cure of Ascites, due to Cirrhosis of the Liver, by Peritoneal Anastomoses.—Dr. B. FARQUHAR CURTIS of New York exhibited this patient, but for lack of time did not report the case in detail.

M. S. Apply.

—HARE.

Chloral hydrate should be exhibited with great care.

Eye-washes of nitrate of silver, if long used, discolor the eye.

Children are especially susceptible to the narcotic effects of opium and its alkaloids.

Be cautious in giving atropine to flaxen-haired, light-complexioned, nervous women.

Medicines administered by the rectum or vagina should be given in twice the dose by the mouth.

Be cautious in giving morphine subcutaneously after opiates have been given by the mouth or rectum.

Medicines administered by the hypodermic method should be given in one-half the dose by the mouth.

Eye-washes containing acetate of lead are apt to leave a permanent opacity where there is any ulceration.

The healthy mucous membrane of the bladder never absorbs medicine; an ulcerated vesical mucous membrane does.—*M. A. Blanton.*

Always direct that iodide of potassium be taken in milk Large doses are then well borne.

Dr. Champlin says that when in doubt as to whether you have a case of gonorrhœa in the female remember that the pus of specific vaginitis is alkaline. Litmus paper will decide the diagnosis.

In treatment of burns of the face, collodion, one part, to castor oil, two parts, painted on will be found efficient and pleasant.

In erysipelas the following evaporating lotion has achieved good results: Carbolic acid, ½ dr.; alcohol and water, of each, 4 oz.; apply to area every alternate hour.

An old physician claims to have relieved the most obstinate cases of tympanitis by placing the patient in the knee-chest position.

In failure of the voice from mucous laryngitis or from fatigue, Bartholow recommends small doses of dilute nitric acid given largely diluted every two hours.

An old physician says that a decoction of quassia, to which a little borax and glycerin, has been added, will remove lice and other parasites from the hair better than any other known remedy.

It is said that ten drops of tincture of cannabis indica and of nux vomica in 1 oz. of chloroform water will produce a voracious appetite.

Dr. S. T. Yount claims to have cured five cases of goiter without a failure by the administration of ten drop doses of tincture of strophanthus, t. i. d.

Dr. Aumaitre claims that salicylate of sodium in doses of 2 or 3 gr. twice daily has cured many cases of whooping cough.

In scrotal eczema an ointment of calomel in vaseline has proved valuable, also an ointment of resorcin 20 gr. to 1 oz. of vaseline.—*Journal of Medicine and Science*, July, 1901.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending October 12, 1901:

	Cases	Deaths
Measles	71	1
Diphtheria and croup	243	40
Scarlet fever	104	9
Smallpox	7	2
Chickenpox	8	..
Tuberculosis	291	164
Typhoid fever	115	27
Cerebrospinal meningitis	..	

The Medical Men of the First Pan-Hellenic Congress.—Greece, this year have followed the example of their brethren in the West, and have held a medical congress. In many respects, the Greek physicians have shown themselves in advance of those of Europe and America, that is if the doings at the Congress may be taken as a criterion. The three subjects chiefly discussed were tuberculosis, alcoholism, and syphilis. The first of these diseases would seem to be active to an amazing degree in Greece, when we take into consideration the fact that the majority of its inhabitants dwell in the country and that nowhere is the population dense. The death rate from tuberculosis in Athens is 40 per 1,000, while Spa—though situated in the midst of those "Isles of Greece" made the theme so often of the poet's praise and whose climate has been vaunted by the sweet singers of all ages.

Greece comes next to Russia among European countries in its mortality rate from consumption.

Alcoholism is not prevalent in Greece, for, although a large amount of strong drink is consumed, it is mainly in the form of wine, which fortunately, not as in countries much more civilized, is comparatively free from adulteration, and can, therefore, be taken with more or less impunity.

The members of the Congress were of the general opinion that syphilis is increasing in Greece, and that stringent measures should be adopted to prevent its further spread.

The Congress not only calls upon the Greek government to take energetic steps against tuberculosis, alcoholism, and syphilis, but to pass acts such as the following:

1. That before marriage both man and woman be required to produce certificates of health signed by two physicians before a magistrate in the presence of two witnesses.

2. That any physician who publishes, in the daily press or otherwise, his discovery of a drug which will radically cure disease, but the nature of which cannot be revealed, shall be liable to prosecution and fine unless the drug be chemically and clinically tested and found to be valuable.

3. That any physician who advertises himself in the press or otherwise [illegible] the [illegible] of the public or publishes matter not in accordance with social ethics or the dignity of the profession shall be liable to a severe penalty.

Thus it will be seen that the first Pan-Hellenic Medical Congress has signalized its opening session by the advocacy of measures which [illegible] hinted at by a few [illegible] at the congresses of the leading scientific [illegible] have not as yet received the approval of the [illegible] of the profession.

The [illegible] *Practitioner* [illegible] editorial comments are [illegible] [illegible] and entertaining [illegible] the British medical journals. The writer of these [illegible] [illegible] and [illegible] words a [illegible] [illegible]. The view taken by the [illegible] upon Koch's latest pronouncement is characterized by sound [illegible] sense and should commend itself to the attention of American readers. In the issue of September Professor Koch's opinion at the British Congress on Tuberculosis is referred to in the following terms: "It is interesting, but scarcely surprising, to note that the discovery that bovine differs from human tuberculosis, with which Professor Koch startled the world, is neither new nor original. In 1898, Professor Theobald Smith of Harvard reported in the *Journal of Experimental Medicine* (Vol. III, page 451) he discovery of certain cultural, morphological, and pathogenic differences between human and bovine tubercle bacilli. His practical conclusion was that, although the bacillus found in the human sputum was incapable of securing a foothold in cattle the bovine bacillus might pass to the human subject. This leaves Koch no point of originality but the reckless suggestion, on the most shadowy evidence that, because human tuberculosis could not experimentally be communicated to animals, bovine tuberculosis cannot be transmitted to man. Since 1898, investigations have been carried out under the auspices of the Philadelphia Live Stock Sanitary Board, for the purpose of comparing tubercle bacilli of human and bovine origin, respectively. Dr. R. R. Dinwiddie of the Agricultural Experimental Station of Arkansas has made a close study of the subject with similar results.

Uric Acid.—Frank Billings (*Illinois Medical Journal*, September, 1901) concludes that: (1) Uric acid probably does not exist in the blood in health. (2) Uric acid is probably formed in the kidney from two sources: (*a*) From urea interacting with some antecedent of urea, probably glycocine in the kidney. The large amount of uric acid excreted by birds and reptiles and the presence in the blood of these animals of urea and not uric acid points rationally to this source of uric acid in these animals, and it is rational to infer that a part at least of the uric acid excreted by mammals including man, is formed in the kidney in this way. (*b*) From the nucleins of the body by oxidation probably in the kidney. (3) That uric acid is not poisonous. That the presence of uric acid in the blood as the quadriurate or biurate probably means that it has been absorbed from the kidneys. (4) That defective kidneys are the cause of the accumulation of urates in the blood because of insufficient excretion. (5) That antecedent kidney disease is commonly found in so-called lithæmic states which have often been attributed to the irritating effects of uric acid upon the kidney capillaries and the cells of the tubules. (6) That the lesions formerly attributed to uric acid are probably due to the toxic effect of the alloxuric bases. (7) That the presence of these lesions in the kidneys and in the connective-tissue elements of the body leads not only to accumulation of the urates in the blood, but also furnish a proper condition of tissue for the deposition of the urates as concretions in joints and fibrous tissues. (8) That the degree of alkalinity of the blood has no influence upon the presence of the urates in the blood. (9) That the deposited biurate concretions cannot be redissolved out of the tissues by an attempt to increase the alkalinity of the blood and fluid by the use of alkaline medication. (10) That the presence of the concretions of the urates in the body comprise the sum total of its harmful effects. (11) That the so-called uric-acid diathesis, the influence of heredity, the bad habits of life, alcoholic indulgence, lead poisoning, etc., [illegible] [illegible] tendency to disintegrate [illegible] of nuclein [illegible] excess of the amount usually [illegible] [illegible] increase of uric acid and alloxuric base formation.

Pure Milk in Leipsic.—Germany has within the past [illegible] [illegible] in matters sanitary, and at the present is [illegible] the country in which laws relating to the health of the community are most numerous and most stringently enforced. The manner in which the supply of pure milk is assured in Leipsic is a case in point. In the [illegible] *Times-Democrat* a recent visitor to Leipsic relates his experiences: "In

Leipsic," he says, "they are very careful. Stables must be kept clean. The person who keeps cows must be experienced in the business. They are particularly careful about the cows that give milk used in feeding children. In order that no mistake may be made, the rules governing the dairy business require the cows to be branded. The rules provide for an injection of tuberculin, and the cow to be healthy must show no reaction after the injection. The injection takes place before the cow is placed in the stable. If a cow should happen to get sick, the fact must be immediately reported, and the veterinary surgeon who has charge of this matter reports the case to the council. The sick cow is generally isolated. This matter, however, is discretionary with the surgeon, who superintends the business. The veterinary surgeon has such complete supervision of these matters that he can even pass on the food given to the cows, and can reject any part or all of it if he pleases. But there is another point. The person who does the milking must furnish a physician's certificate to the effect that he or she is free from infectious or nauseous diseases, and tuberculosis is especially mentioned in the rule. The milk is strained and centrifugally purified, and must be thoroughly cooled before it is served to the customers. If the milk is sold in bottles, patent stoppers are used. All these requirements have more particular reference to the milk furnished babies. There is one thing probably more important than any other in this connection, and that is in the matter of food. Cows which give milk, used in nourishing babies, are given only dry food, such as hay and meal, and they are never allowed to use the pastures. They must be kept in the stables, and in this way the *healthiest* and purest milk possible is served to the infants of the country.

Modern Treatment of Cough. In an article in *Heilkunde*, a publication of Vienna, Weiss says that expectoration depends on two points: (1) The expelling power of the air, and (2) the resistance offered by the substance which is to be removed, depending on adhesion and inertia. The expelling speed of the air varies considerably. In quiet respiration it passes through the glottis at 125 cm. per second, and the pressure supports 2 mm. of mercury. During violent expiration and severe coughing, the pressure rises to 150 to 200 mm., and the speed is said to exceed that of the wind in a storm. It is said to be as much as 100 meters per second. Of course, during the passage through the bronchi, etc., the speed is much less. These experiments show that there is a great deal of work done in violent coughing, and how exhaustive coughing is, especially if it prevents the patient from sleeping. External atmospheric conditions have an important effect on coughing; with a low barometer the conditions are much more favorable than with a high reading, hence the value of a mountainous region, with a permanent low pressure. In treating cough, our first endeavor should be to remove any cause, reflex or otherwise. It is not necessary always to stop coughing. In certain cases you aid it, by loosening the tenacity of the mucus by expectorants, or by other treatment. Apomorphine is probably the best drug. Great good can be done by such simple means as keeping the atmosphere moist, and thus preventing the secretion from becoming dried and tenacious. This can be effected by keeping a kettle boiling, or by some of the various inhalation apparatus. We must modify coughs by narcotics, as morphine, which dulls the center in the medulla, and by heroin, which lengthens both inspiration and expiration, thus allowing the moistened air more effectually to penetrate the bronchial tree. Heroin is best given in pills. Dionin, another morphia derivative, seems to resemble morphine very much in action, relieving pain as well. The author thinks that belladonna has been too much neglected, as it stimulates the respiratory center, and paralyzes the smooth muscle fibers, and inhibits the secretion of glands. It is chiefly to be used to deprive cough of its cramplike character, as in whooping cough. Weiss considers that the combination of expectorants and narcotics is wrong. They should be given separately, the narcotic being given for special indications, as pain, sleep, etc.

Tuberculous Passengers on Railways.—This subject has been much discussed of late, and various methods have been recommended to prevent the dissemination of tuberculosis by a railway passenger suffering from the disease. Dr. George Chaffee, surgeon to the Long Island Railway, writing in the *Railway Surgeon* for July, 1901, suggests, among other safeguards, the following precautions: (1) To instruct the public in methods of prevention, (2) co-operation with boards of health; (3) the enactment of proper legislation, both State and national. A national law protects the various seaport towns of this country, and ever stands to support our health officers whenever they find it necessary to quarantine cases of smallpox, cholera, and yellow fever. Why should not a national law as well give tuberculous passengers the right to ask for a private room, or a compartment of a car—which is only another name for it—and also notify railway corporations to have these private rooms, or compartments, ready for immediate use when needed; thus protecting healthy passengers from infection, disease, and an untimely death. The railway men of this country stand at the head in the matter of business intelligence and enterprise, and I am satisfied that they will be found ready and willing to carry out their part of any legislation that may be enacted for the prevention of tuberculosis. It would seem to be only just and right that there should be national legislation on this subject whereby railway corporations might be requested to furnish compartment cars and at points near health resorts entire sanitary cars, and which would oblige tuberculous passengers to occupy such compartments, and to comply with all the requirements of such a law. Such a law should provide for the disinfection of every compartment or sanitary car at the end of every run, if it has been occupied by a tuberculous passenger, and a record made and filed of the disinfection.

A Faith Curist in Russia.—The *Novoe Vremya* of September 14 has the following account of a miracle performed by the famous Father John of Cronstadt: "On the 12th, Father John arrived at the village of Sopino, conducted service, and spent the night with Father Lvov. Next day he journeyed to Konchanskols and consecrated the new stone church there in the presence of fully 10,000 people. After this service, a breakfast was given in the school, and many speeches were delivered. In the midst of the breakfast, two men and two old women were seen approaching the schoolhouse, bearing the seemingly lifeless body of a woman. For seven years this woman had been paralytic, unable to move arms or legs or to open her eyes—was a living corpse. On their bringing her to him Father John arose, stood before her, and, asking her name, gazed fixedly at her. Then in a loud voice he bade her open her eyes. After several attempts, Audotya (the paralytic) did so. 'Look me straight in the face,' said Father John, 'and cross yourself.' Slowly and with great effort the woman succeeded in making the sign of the cross. 'Do it again,' said Father John, 'and again.' With ever-increasing faith, the woman repeated the movement. 'Stand up,' said Father John, and the woman arose. Then he moved from his place, bidding her follow. 'Now walk around me,' said Father John, and the seemingly dead woman slowly approached and fell on his shoulder. 'Go and pray,' said he, blessing the woman. On this, she moved away without any help. All this took place in the presence of thousands, who were unable to restrain their tears."—*Pall Mall Gazette*.

Opinions of British Lay Journals on Professor Koch's Recent Paper.—The London *Times* says: "On one point Professor Koch elicited some expressions of dissent which will be widely echoed in the medical world. He is convinced that tubercle in man is a different thing

from tubercle in cattle, that the two things are not interchangeable, and therefore that elaborate precautions against tuberculous milk and meat, are thrown away. He has made some experiments, which Lord Lister admits to be conclusive, to show that human tuberculosis is not transmissible to cattle. It does not follow, however, that bovine tuberculosis is not transmissible to man. Direct experiments, of course, cannot be made as in the converse case, and while Professor Koch brings forward much evidence of an indirect kind in support of his contention, there is also much that certainly points to the possible production of consumption in the human subject by the ingestion of tuberculous meat or milk. Professor Koch does not appear to have directly demonstrated a difference between the bacteria in the two cases, though such a demonstration would be peculiarly in the line of so accomplished a bacteriologist. Until that is done, it would be rash to assume that bovine tuberculosis cannot produce tuberculosis in man; but Professor Koch has certainly opened up a question which had been regarded as practically settled, and has adduced arguments too weighty to be set aside, merely because they clash with accepted opinions. It would simplify many things if he were proved to be right. In the meantime his paper will, no doubt, lead to much re-examination and resifting of evidence, as well as to efforts to make more exact experiments.

Concerning Congresses.—In commenting upon the suggestion that a congress be convened to devise means for combating the increase of malignant disease, the *Medical Press and Circular* says that many persons regard a congress, or at least a commission of inquiry, a panacea for ignorance on any subject. "They attribute to these bodies sundry occult powers of discovering the truth, and, having voted in favor thereof, they fold their hands in the blissful consciousness of having done something to help the cause. Scientific men, on the contrary, are disposed to question the gain to knowledge of these ever-recurring congresses. It is difficult to define in these days of international journalism the way in which these gatherings can advance our knowledge of the subjects under discussion. If anything new or interesting crops up which is quite exceptional, it simply means that a particular investigator has held over his communication in view of the meeting. Truths are not elucidated in view of a congress, and failing such a meeting they would be communicated to the scientific world by the ordinary channels, which, after all, are better suited to the purpose. Of all subjects in the world in respect of which a congress would be futile and indeed absurd, cancer is the least amenable to discussion. What we require is fact, not discussion, and facts are being strenuously sought after by hundreds of trained intelligences throughout the civilized world. No stimulus is needed in the way of prizes or rewards; the privilege of having been able to throw light on this dark corner in pathology would be, in itself, ample compensation for a lifetime devoted to laborious research."

Congress on Seasickness.—The Tuberculosis Congress says the *American Review of Reviews*, September, 1901, is only one of this season's European gatherings of specialists for the consideration of some malady or ill against which it is hoped that scientific men, through study and co-operative method, may be able to provide a remedy. In August, there was held at Ostend under the patronage of the municipal administration, and under the high protection of the King of the Belgians, a special exposition of all methods that have been devised, or proposed, to prevent or mitigate sea-sickness, and also a congress to discuss that much-joked-about but very serious and troublesome form of illness. As travel by water becomes more and more general and inviting, the one drawback that spoils it all for myriads of voyagers is the liability to seasickness. The plans of the exposition provided for six departments or sections, one of which belonged to naval architecture, and had to do with means to diminish the effect of the movement of ships. Another section was devoted to means for improved ventilation of vessels, the removal of odors, and the abundant supply of oxygen. Other sections had to do with the use of various hygienic or other means of prevention or remedy by the individual traveler, and a final section was devoted to a collection of the very considerable literature, in all languages, relating to the subject. Doubtless results of some consequence will have followed from these efforts of that useful French society known as the "Ligue contre le Mal-de-mer."

Treatment of Menorrhagia in Young Girls.—A. G. Wollenmann (*Der Frauenarzt*, August, 1901), says that the patient must remain in bed during the entire period of the menstruation and must not leave it until twenty-four to forty-eight hours after the entire disappearance of the flow. The patient must lie on her back without moving the arms and legs. Meals are to be taken in bed. These regulations are difficult to carry out, and yet they are the only ones giving positive results. During the first month's treatment, the duration of the flow is diminished by a day or two; this improvement becomes more marked with every month, and cure is effected as a rule in five or six months. When these girls leave their bed, all physical and mental exertion must be forbidden. Long walks, dancing, bicycling, horseback riding, and machine sewing must be given up for a time and returned to gradually after the cure. The general condition with its eliminative and assimilative functions must be improved. Balls, parties, or theater are absolutely forbidden. Cold douches and massage stimulate the activity of the skin. All highly seasoned food stuffs, alcohol, strong coffee and tea—in short, everything which tends to irritate the nervous system or leave the system loaded with toxins—are to be avoided.

Sanitation of Cuba.—A Cuban physician, Dr. A. Bustillo Lirola, writes in the *Annals of Gynecology and Pediatry* on this subject. He compares the conditions prevailing in the island under Spanish rule and under American, needless to say, greatly in favor of the latter. He says: "We can proudly say that Cuba is hygienized. This could be possible, because the true Cuban population have aided greatly in it. Yellow fever has diminished in such a notable way that this fact alone is noteworthy. During last June there has not been a death from yellow fever, nor even a case of the disease. Records show that since 1781, no previous June has passed with absolute freedom from the disease. Infectious diseases, as a rule, are less frequent. With the war on mosquitos, malarial fever has also diminished. Leaving out of consideration the death rate from 1895-1898, if the number of deaths during the year 1900 is compared with that of the years previous to 1895, we shall find that they are much less now. This is valuable testimony to the efficient efforts made under American occupation to render Cuba healthy, the more so, coming, as it does, from an impartial source."

Disinfection of Public Dwellings and Conveyances.—*The British Medical Review of Reviews*, September, 1901, says that railway carriages, steamboats, and hotels should be disinfected. This would be of truly international importance. The Minister of Public Works in France has recently sent a circular to railway companies calling attention to the precautions necessary to diminish risk of contagion. The Minister of the Interior, Germany, has enacted a measure whereby every doctor who attends in a case of pulmonary or laryngeal tuberculosis is bound to report the fact to the police. After a death from tuberculosis, the room of the patient and his belongings have to be disinfected. Hotel proprietors, furnished-house keepers, asylums, and other public institutions are compelled to report every case of tuberculous disease in their establishments

THE PREVENTION OF YELLOW FEVER.*

BY WALTER REED, M.D.,
SURGEON, U. S. A.,
AND
JAMES CARROLL, M.D.,
CONTRACT SURGEON, U. S. A.

THE prevention of yellow fever since its first importation into the United States in 1693, and especially during the latter half of the past century, has commanded, perhaps, more attention on the part of those who were concerned with matters pertaining to the public health than the prevention of any of the other acute infections. This has not been occasioned by the fact that its total sickness and mortality have exceeded that of other acute infectious diseases, such as typhoid fever or croupous pneumonia, but because rather of the proximity of its source to our shores; the lack of knowledge of its specific agent; the consequent mystery surrounding its origin and propagation; the alarmingly rapid spread and course of this disease, when once it had obtained a foothold, and the high mortality with which its epidemics have generally been attended. Although the duration of its presence in our seaports was plainly limited by certain seasonal conditions, yet during its brief reign —July to October—its ravages were such as to completely paralyze both the social and commercial interests of a given city, and even of an entire section of our country.

The interval between 1793 and 1888 is almost one hundred years, but upon the appearance of yellow fever we observe no difference of behavior on the part of the inhabitants of Jackson, Miss., in 1888, from that shown by the citizens of Philadelphia in 1793, except that the terror of the former was greater and their flight from their homes more precipitate than in the case of the latter.

The recurrence of succeeding epidemics has, therefore, served to increase rather than to lessen the public alarm.

It would be difficult to determine with accuracy the loss of life occasioned by the ninety-five invasions of our territory by yellow fever during the past two hundred and eight years. We have endeavored to collect from the most available sources the mortality caused by this disease, but have been unable to obtain any reliable data for the earlier epidemics. If we confine ourselves to the epidemics which have occurred since 1793, we find that there have not been less than 100,000 deaths from this cause. The greatest sufferer has been the city of New Orleans, with 41,348 deaths, followed by the city of Philadelphia with 10,038 deaths. The epidemics of 1855, 1873, 1878, and 1879 claimed 7,759 victims in the city of Memphis, Tenn. From 1800 to 1876, Charleston lost 4,565 of its citizens by attacks of yellow fever. New York, during the earlier and later invasions of this disease, has had 3,454 deaths, while the epidemic of 1855 in Norfolk, Va., caused over 2,000 deaths. During our brief occupation of the Island of Cuba (July, 1898-December, 1900), with every precaution brought into exercise to ward off the disease, there have occurred among the officers and men of our army, 1,575 cases of yellow fever with 231 deaths.

If we reckon the average mortality at 20 per cent., there have not been less than 500,000 cases of yellow fever in the United States during the period from 1793 to 1900.

Turning for a moment to other countries, we find that the great epidemic of 1800, in the province of Andalusia, Spain, caused 60,000 deaths, and that 20,000 more deaths attended the invasion of the city of Barcelona by this disease in 1821. From 1851 to 1883, the deaths from this cause in the city of Rio de Janeiro were 23,338, while in the city of Havana, between the years 1853 and 1900, 35,052 deaths have been recorded from yellow fever.

We have no means of computing the damage done to the commercial interests of the United States by epidemics of yellow fever. At the sixth annual meeting of this association, held in Richmond, Va., in 1878, Dr. Samuel Choppin, President of the State Board of Health of Louisiana, estimated the actual cost of the epidemic of that year to the material resources of the city of New Orleans as $10,752,500. Dr. Benjamin Lee, the present distinguished occupant of the presidential chair, at the seventeenth annual meeting of this association, held in Brooklyn, N. Y., in 1889, contributed a paper having the title, "Do the Sanitary Interests of the United States Demand the Annexation of Cuba?" From this we quote the following sentence: "A single widespread epidemic of yellow fever would cost the United States more in money, to say nothing of the grief and misery which it would entail, than the purchase money of Cuba." That this was no exaggeration, witness the language of the petition which the chairman of the committee on the etiology of yellow fever, in conjunction with other prominent members of this association, presented to the President of the United States on November 15, 1897, and again, on November 21, 1898, in accordance with a resolution adopted at the meeting of this association, held at Ottawa, Canada, in 1897. In addressing President McKinley, Dr. Horlbeck said: "It is hardly necessary to call your attention to the serious results of the recent epidemic of yellow fever in the States of Louisiana, Mississippi, and Alabama, but we may be permitted to mention the fact that the great epidemic of 1878 resulted in the loss of nearly 16,000 lives, and that it has been estimated that the total loss to the country resulting from this epidemic was not less than $100,000,000."

The importance of the study of the causative factors entering into the propagation of a disease so capable of quickly destroying the lives of the citizens and wrecking the commercial interests of the cities of the United States could hardly be overestimated. Did time permit, we would be glad to refer to the numerous and valuable contributions made to this subject by the members of the American Public Health Association. We can only mention the establishment of the National Board of

*Read at the twenty-ninth annual meeting of the American Public Health Association, held in Buffalo, N. Y., September 16–21, 1901.

Health and the appointment of the Havana Yellow Fever Commission of 1879 as two of the most important outcomes of the persistent efforts of this association, following "the deeply tragical events of the summer of 1878." The exhaustive reports made by Chaillé in 1880, and by Sternberg in 1890, must always stand as monuments to the earnest

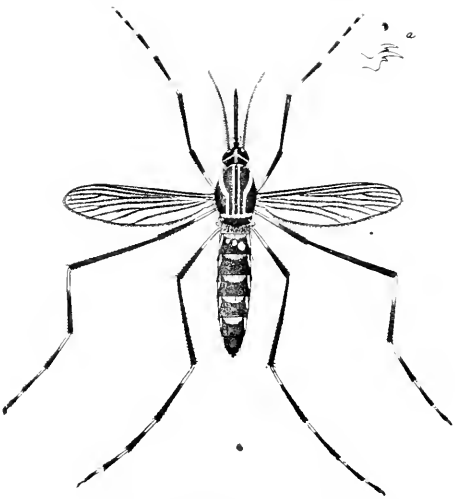

FIG. 1.—Stegomyia Fasciata, Female. *a*, Front tarsal claw.

spirit of investigation with which the work was pursued.

Notwithstanding the importance of the work and the efforts put forth by students in this and other countries, we believe that we are safe in saying that no results had been obtained which would enable us to combat successfully this disease when once imported into our larger centers of population, and no means found to keep it out of our ports except such as would place very heavy burdens upon commerce. This inability to control the disease grew not only out of our ignorance as to the way or ways in which yellow fever was propagated, but also out of certain false opinions which we had formed as to the mode of its spread. The doctrine of the spread of yellow fever by fomites and by filth had taken such hold on the professional mind as completely to overshadow all other views, and to direct into false channels the work of those who were engaged in the investigation of this disease. The efforts to isolate or to discover the specific agent of yellow fever, if successful, would possibly have greatly simplified the problem; in the absence of such discovery, the first step in our knowledge of how to prevent this disease could only be found, we think, along another line, viz., that of its propagation from the sick to the well. This step we endeavored to take, in connection with our colleagues, Dr. Agramonte and the late Dr. J. W. Lazear of the United States Army, during our recent investigations into the causation and spread of yellow fever at Quemados, Cuba.

The results of our earlier work relative to the etiology and propagation of this disease we had the pleasure of presenting to this association at its last meeting, held in Indianapolis, Ind.[1] You will recall that one of the conclusions which we then submitted was as follows: "The mosquito serves as the intermediate host for the parasite of yellow fever." In the same article, we briefly indicated the reasons which influenced us in pursuing this line of investigation, and it is, therefore, unnecessary here to repeat them.

Continuing our studies, especially as regards the means by which yellow fever is spread from individual to individual, and as to the manner in which houses become infected, we were able, under strict rules of isolation and quarantine, to bring about an attack of yellow fever in ten non-immune individuals (and always within the period of incubation of this disease) out of a total of thirteen (76.84 per cent.) whom we attempted to infect by means of the bites of mosquitos—*stegomyia fasciata*—that had previously been fed with the blood of yellow-fever patients during the first, second, and third days of their attacks. These results were reported in part to the Pan-American Congress held in Havana during February of this year,[1] and in part to the Association of American Physicians at its last meeting held in the city of Washington.[2]

It will be seen that we were able to establish in the most conclusive manner that the mosquito does serve as the intermediate host for the parasite of yellow fever. At this same Experimental Sanitary Station we were, also, able to demonstrate that an attack of yellow fever cannot be induced by the most intimate and prolonged contact with the clothing and bedding of yellow-fever patients, even though these articles had been previously thoroughly and purposely soiled with the excreta of such patients. In other words, we were able to prove that the garments worn, and the bedding used, by yellow-fever patients were no more concerned in propagating this disease than the clothing and bedding of patients suffering from malarial fever are concerned in the spread of the latter malady. The doctrine of the spread of yellow fever by fomites having, at the first touch of actual experiment on human beings, burst like a bubble, we may hereafter cast it aside, with

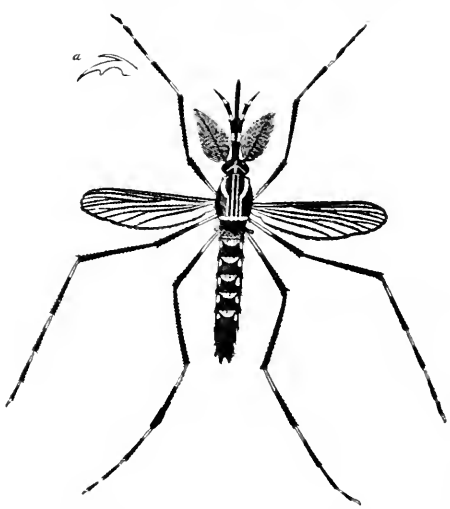

FIG. 2.—Stegomyia Fasciata, Male. *a*, Front tarsal claw.

other exploded beliefs, to the very great simplification of the problem how to prevent yellow fever. Indeed, in our opinion, the time has now arrived

[1] "The Etiology of Yellow Fever—A Preliminary Note," *Philadelphia Medical Journal*, October 27, 1900.

[1] "The Etiology of Yellow Fever—An Additional Note," *Journal American Medical Association*, February 16, 1901.

[2] "Experimental Yellow Fever," *American Medicine*, July, 1901.

when the latter problem may be reduced to measures which shall prevent the propagation of this disease by mosquitos. Although the specific agent of yellow fever has not, as yet, been discovered, this must remain largely a matter of scientific interest, and does not, in the least, lessen the efforts which we, as sanitarians, are now able, for the first time, to bring into action for the prevention of the spread of this disease, since, in dealing with the mosquito, we are dealing with the intermediate host which carries the specific agent from the sick to the well.

In considering, then, in a broad way, the preven-

Fig. 3.—Stegomyia Fasciata. Batch of fifty [illegible] deposited by a single female. Slightly enlarged.

tion of yellow fever, the natural order would be to give our attention, first, to measures which will prevent the importation of this disease from infected places into the seaports of the United States; and, secondly, to measures which will most effectually prevent the spread of this disease, provided it should gain a lodgment in one of the cities of this country.

With your permission, however, we will reverse the order of consideration above suggested, and will later refer in the briefest manner to the prevention of the importation of yellow fever into the United States from foreign ports, as this part of the subject will be presented by the Health Officer of the Port of New York, who, from long experience, will be able to deal more intelligently than we with this part of the problem.

Since the mosquito, especially that species of stegomyia which has recently been designated by Theobald as *stegomyia fasciata* (formerly known to entomologists as *culex fasciatus*—Fab.), has become so prominent a factor in the spread of yellow fever, it becomes necessary to consider this insect from the point of view of its identification; its habitat; its breeding places; the length of its generation; its hours of feeding; the influence of temperature upon both its propagation and stinging; the interval after contamination before the insect becomes capable of propagating the disease; the length of time during which

Fig. 4.—Stegomyia Fasciata. Forty-eight eggs deposited in a close-lying mass. Enlarged.

it remains dangerous; the measures that should be used not only to protect the sick against the bites of these insects, but also to prevent the latter from infecting the healthy individual; and, finally, a consideration of the several agents which may be successfully employed both to prevent the breeding of mosquitos as well as directed toward their destruction in the adult stage.

Aside from the standpoint of scientific interest, it is certainly a matter of hygienic importance, in taking up the question of how to prevent the spread of yellow fever, when imported into the United States, that the health authorities of our several coast cities, and, indeed, of some of our inland towns, should be able to determine whether the only species of mosquito, which, up to the present time, has been shown capable of conveying yellow fever, is or is not present in these cities. If it should hereafter be proven that only species of the genus *stegomyia* are capable of acting as intermediate hosts for the specific agent

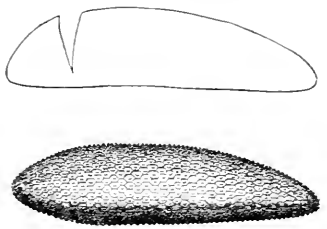

Fig. [illegible] Stegomyia Fasciata. [illegible] deposited eggs. [illegible] a Empty shell or [illegible] which larva has escaped.

of yellow fever, as appears to have been demonstrated for the genus *anopheles* in the spread of malaria, the presence or absence of the former genus will definitely determine whether yellow fever will or will not spread in a given locality. The presence or absence of mosquitos that can propagate the disease is the only intelligible explanation of what has heretofore been considered an inexplicable problem, viz., the capability of this disease to propagate itself in certain localities, while in other places it

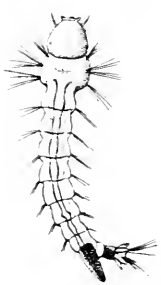

Fig. [illegible] Stegomyia Fasciata. Full-grown larva enlarged.

could be introduced with perfect impunity to the public health. In other words, our present knowledge of this question solves, at last, the problem of the portability or non-portability of yellow fever.

Description of Mosquito.—The identification of *stegomyia fascia.a*—Theobald—should not be difficult. This mosquito, when examined closely with the naked eye and especially with a pocket lens, is

Fig. 5.—Stegomyia Fasciata. Pupa [illegible] enlarged.

a rather striking-looking and handsome insect. Fig. 1. Its most conspicuous markings are the broad semi-lunar silvery stripe, which is seen on the lateral surface of the thorax, and the white stripes at the bases of the tarsal joints. These may be readily distinguished with the naked eye. The bands on

the hind legs are especially well marked, and occasionally the entire fifth hind tarsal joint is seen to be of a pure silvery white. The four stripes of silvery scales which are seen on the posterior surface of the thorax serve to distinguish this species from all other mosquitos, except *stegomyia signifer*—Coquillet—in which, however, as we have been informed by Mr. L. O. Howard, the curved thoracic band is very narrow and of a somewhat different shape. Examined with a hand lens, the four stripes are seen to consist of two lateral, distinct silver lines—the continuation of the semi-lunar, broad stripes—and two fine, white lines situated between these, and which require that the insect shall be held in the proper light, in order that these delicate threads may be distinctly seen. The lateral surface of the thorax is also marked by several silvery dots and the abdomen by distinct white stripes. This description applies to both sexes. In the female, the palpi are short, as in the genus culex. The proboscis is of a dark blackish-brown color and is destitute of a whitish band near the middle. In the male (Fig. 2), we have recently received specimens of *stegomyia fasciata* through the courtesy of Dr. T. O. Oertel of that city. Dr. Durham of the English commission for the study of yellow fever kindly showed us specimens of this insect which he had collected at Parà, Brazil, and at various places along the Amazon River. It will be seen, therefore, that *stegomyia fasciata* has a wide distribution in the warmer countries of the globe, and especially at low altitudes. A more exact knowledge of the distribution of this mosquito in the United States is, we think, a matter of considerable practical importance.

Breeding Places.—In our search for the larvæ of this insect we have found them in the following places: (1) In rain-water barrels; (2) in sagging gutters containing rain water; (3) in tin cans that had been used for removing excreta and which still contained a small amount of fecal matter; (4) in cesspools; (5) in tin cans placed about table legs to prevent the inroads of red ants; (6) in the collection of water at the base of the leaves of the *agave americana*; (7) in one end of a horse trough

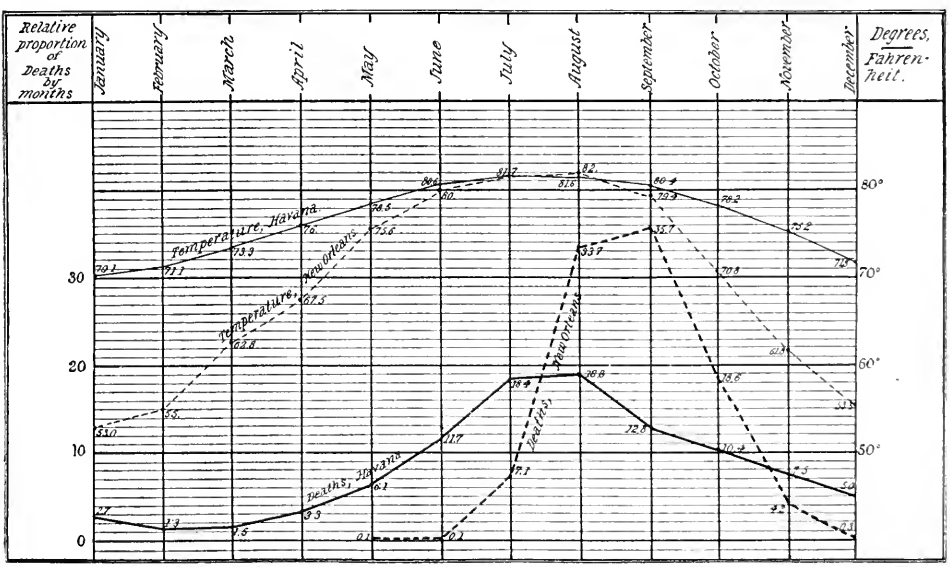

FIG. 8.—Chart Showing the Mean Monthly Temperature of New Orleans and Havana for Ten Years; and the Relative Monthly Mortality from Yellow Fever in Havana from 1880 to 1890, and in New Orleans from 1847 to 1897.

one of the front tarsal claws bears a tooth on the under side, while the other claw is destitute of such marking. In the female, both front tarsal claws bear a distinct tooth near the base of the under side of each.

Habitat.—We have found this mosquito in all of the principal cities of Cuba, and have received specimens from a number of the smaller towns on this island. According to Howard[1] it has been found at Kingston, Jamaica, on the Isle of Pines, and at Bluefields, Nicaragua. He also reports that Theobald has received specimens of this insect from Italy, Greece, Spain, Portugal, Gibraltar, and Malta. In the United States, Howard reports its presence at New Orleans, Natchitoches, and Napoleonville, La.; in Eastern Texas; Hot Springs, Arkansas; Pelham, Ga.; and from Virginia Beach, near Norfolk, Va. To this we can add Augusta, Ga., from which city

[1] "Mosquitos," etc., by L. O. Howard, New York, 1901.

that was in daily use. It follows that stegomyia, like culex, will breed in any collection of still water, rain or hydrant, and that the presence of fecal matter does not seem objectionable. Indeed, we have been in the habit of adding a very small quantity of the latter to our breeding jars, as it has seemed to hasten the development of the larvæ. In water, however, which contains much suspended soil—muddy water—the larvæ, in our experience, do not flourish, but die off rather rapidly.

Deposition of Eggs.—The insect lays her eggs during the night, and, unlike culex, which deposits its eggs in boatlike masses, stegomyia extrudes her eggs on the surface of the water in pairs, in groups of three or more, or singly; in this respect resembling anopheles (Fig. 3). Exceptionally, the eggs are deposited in a rather close-lying mass (Fig. 4). The whole batch is laid in one night, or extending over two or three nights. The number of eggs deposited

varies from about twenty to about seventy-five—rarely a larger number. Sixteen careful counts gave an average of forty-seven eggs. At the same time that the female deposits her eggs, she frequently, but not always, discharges a fluid which forms a very thin film over the surface of the water, which possibly assists in floating the eggs. The latter are of a jet-black color and, to the naked eye, cylindrical in shape, one end of the egg being rounded and blunt, while the other is slightly pointed, the whole resembling closely a Conchita cigar. They measure about .65 mm. in length by .17 mm. in width, at the broadest part. Under a low power, the surface of the eggs is seen to be marked by tolerably regular six-sided plates, each of which is further marked in the center by a little round elevation, which gives to the surface of the egg a decidedly roughened appearance (Fig. 5). Under this low amplification it is also seen that, while one side of the egg is somewhat convex, the other is flat or slightly concave and that a cross-section of the egg would present the appearance of a triangle instead of that of a cylinder. This flattening of the surface of the egg does not appear to extend quite to the ends, which are round in shape. Although floating perfectly if left undisturbed, any agitation of the water, especially of a rough character, is apt to cause some or a majority of the eggs to sink. If by slight pressure the egg is pushed beneath the surface of the water, it at once sinks and does not rise again. This sinking of the eggs does not interfere with their subsequent hatching, as in our experience submerged eggs furnish about as many larvæ as those which are left floating on the surface.

The resistance of stegomyia's eggs to external influences is worthy of note. Drying seems to be but little injurious to their subsequent fertility. We have found that eggs dried on filter paper, and kept for periods of from ten to ninety days, will promptly hatch when again submerged in water. Dried eggs brought with us from Havana, in February, were easily hatched during the month of May, in Washington, furnishing about 60 per cent. of the usual number of larvæ hatched from fresh eggs. Freezing does not destroy the fertility of the eggs. Although freezing with a mixture of salt and ice for thirty minutes has several times seemed to prevent subsequent hatching; on one occasion a batch of one hundred and fifty-five eggs, freshly deposited, which were frozen at a temperature of —17° C., for one hour, then thawed out at room temperature and placed in the incubator at 35° C., began to hatch on the sixth day, the majority furnishing active larvæ on the eighth day. In another observation, freshly deposited eggs, frozen at —17° C. for half an hour on two successive days, began to hatch on the third day as usual at incubator temperature. The resistance of stegomyia's eggs to drying for a period of three months would appear to demonstrate that this genus of mosquito could survive the winter in Havana, without the presence of hibernating females. Doubtless the genus is preserved in both ways. It is probable that the same could occur in our extreme southern latitudes.

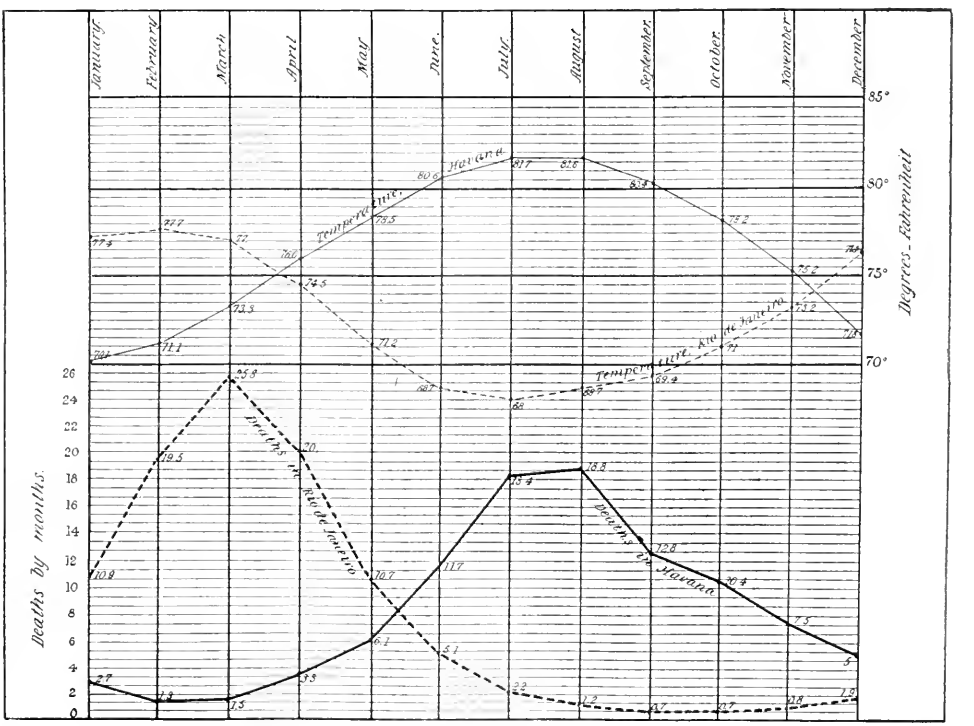

FIG. 9.—Chart Showing Mean Monthly Temperature of Havana and Rio de Janeiro for Ten Years; and the Relative Monthly Mortality from Yellow Fever in Havana from 1889 to 1899 and in Rio de Janeiro from 1851 to 1883.

Length of Generation.—The impregnated female, having obtained a meal of blood, proceeds to deposit her eggs, in captivity, after an interval varying in our experience from two to thirty days—as a rule, the eggs are laid within seven days; sometimes a second or third meal of blood is taken before any

eggs are laid. Eggs placed under favorable conditions of warmth, *i. e.* summer or incubator temperature, begin to hatch, as a rule, on the third day, the period extending to about one week. The larval stage requires seven or eight days, and the pupal stage about two days. The period for the generation may be stated, therefore, as follows: Incubation, three days; larval stage, seven days; pupal, two days; total, twelve days. As the eggs begin to hatch before the expiration of the third day, we generally obtain a few mosquitos on the eleventh day. The shortest period of development observed by us during summer weather in Cuba was incubation, two days; larval stage, six days; pupal, thirty-six hours; making the total length of this generation nine and a half days. This short period we believe to be quite exceptional. The first fully developed insects begin to emerge on the eleventh or twelith day, and the whole number have reached maturity by the fifteenth or eighteenth day after deposition of the eggs. The young larvæ, in emerging, rupture the shell at a point about one-fifth the length of the egg from the larger end. This cap-like end can be frequently seen turned back and still adhering to the rest of the shell (Fig. 5).

The larva and pupa of stegomyia (Figs. 6 and 7) resemble fairly closely those of culex, and the larvæ maintain the same relative position to the surface of the water, *i. e.* while in the act of breathing they assume a vertical position, with the head directed downward.

Influence of Temperature on Propagation.—We have just seen that at summer temperatures the time required for a complete generation of this insect is from eleven to eighteen days. We may say that at an average temperature of 75° F., or over, stegomyia multiplies abundantly. Exposure to a cooler temperature, even for a short time daily, much retards the development of this mosquito. Thus, a batch of fifty-one eggs kept at 35° C., but which were placed in a cool chamber at 20° C. for two hours daily during the whole process of development, although furnishing a few larvæ at the end of the third day, were not all hatched until the eleventh day. The first pupæ appeared on the fourteenth day and the first mosquito on the nineteenth day; the whole process being completed in twenty-seven days, instead of the usual fifteen to eighteen days. The loss of insects was about 50 per cent. Eggs kept at a temperature of 20° C. (68° F.) do not hatch, in our experience. Newly hatched larvæ kept at this temperature develop very slowly and require about twenty days to reach the pupal stage. Mosquitos developed under such conditions are feeble, and but few arrive at maturity. Young larvæ kept at 10° C. (50° F.) have failed to reach the pupal stage—although some growth takes place. In one experiment more than 50 per cent. were dead at the end of two weeks, and none survived the thirty-second day. Half-grown larvæ and pupæ exposed to a temperature of 20° C., and even as low as 10° C., continue to develop slowly, but the few insects which escape drowning have, as a rule, been of feeble strength and have refused to bite. Although the reduction of the temperature to the freezing point, or below, would not necessarily destroy the vitality of the eggs of this genus of mosquito, it should be remembered that a reduction of temperature to 68° F., or below, for even a few hours of the twenty-four, will much retard the development of the generation. At a temperature less than 68° F. the eggs of this insect have ceased to hatch.

Influence of Temperature on Biting.—While the non-impregnated female does not appear to bite, the impregnated female is generally ready to bite on the second or third day of her existence; they very rarely suck blood on the first day. This species of mosquito when not deprived of its liberty, although occasionally biting during the morning hours, has, in our experience, been especially active from the hours of 4 P.M. till midnight. In captivity, the hungry impregnated female will bite at any hour of the day or night. The meal of blood appears to have been thoroughly digested on the third day, when the insects, if applied to the surface of the skin, can be again readily induced to feed. When freed in a room, the female does not appear to bite a second time till about five, or even seven, days have elapsed.

As regards the effect of temperature on the stinging of *stegomyia fasciata*, the results of a number of observations made by us show that this mosquito will bite at temperatures of 62° F. and above. At temperatures below this point, we have not, as yet, succeeded in inducing even very hungry females to suck blood. We may, therefore, say that observations thus far made appear to show that *stegomyia fasciata*, while not breeding at temperatures below 68° F., will still bite at a temperature as low as 62° F., but probably not at lower temperatures.

If this insect is concerned in the propagation of yellow fever, it is now quite apparent why an epidemic of this disease should fall to a low ebb in the city of New Orleans during the month of November, with a mean temperature of 61.8° F., and practically cease in December, with a mean temperature of 55.3° F. A careful study of the charts herewith submitted (Figs. 8 and 9), showing the monthly mean temperatures of the cities of Havana and New Orleans and Havana and Rio de Janeiro, together with the relative monthly mortality from yellow fever in these cities, will prove of interest, we think, as showing better than laboratory observations the general effect of temperature upon the breeding and biting of *stegomyia fasciata*. In the light of recent researches, we can now understand that while yellow fever can, and does, prevail during the entire year in Havana and Rio de Janeiro—although at a comparatively low ebb during the winter months—it cannot propagate itself in New Orleans from December to May.

Interval After Contamination Before the Mosquito Becomes Dangerous.—In our experimental work on human beings, we have not succeeded in inducing an attack of yellow fever by the bites of mosquitos which had been kept less than twelve days after contamination. The same insects which failed to convey the disease on the eleventh day were capable of so doing on the seventeenth day after infection. This interval of about twelve days, which appears necessary for the development of the parasite within the mosquito, plus the period of incubation, agrees with the time that has been observed to elapse between the introduction of an infecting case into a locality and the occurrence of the first secondary case, viz., two to three weeks.

After the mosquito has once become dangerous, how long it remains capable of conveying the disease, although important, has not been determined. We have reported cases of yellow fever caused by the bites of stegomyia at intervals varying from twelve to fifty-seven days after contamination. Here the dangerous interval was forty-five days, but as one of these insects lived until the seventy-first day after biting a yellow-fever patient, the dangerous interval would here be prolonged to fifty-nine days, or a little over eight weeks. In our experience, the infected insect appears to live about as long as the non-infected mosquito, so that the answer to this question would depend upon the length of life of the mosquito. This we do not know. While in captivity, the majority of

mosquitos do not survive, with the best of care, more than about five weeks, and many die within half of this time; we are ignorant as to the length of time during which they may live when under natural conditions. Certainly, during summer weather this will depend largely on the opportunity which the mosquito has of obtaining access to water.

Measures to Prevent the Spread of the Disease When Imported.—A case of yellow fever having been imported into one of our seaport cities, we are now prepared to discuss the measures that should be taken to prevent its spread. The problem resolves itself into the simple one of excluding mosquitos from access to the sick individual and of destroying those insects that have already become infected. We can leave out of consideration any danger from wearing apparel or baggage, which, in our opinion, may be dismissed as harmless.

The fear that has been entertained that infected insects may be imported in boxes or trunks, we believe to be absolutely groundless, and this for the cannot be imported alive in baggage that has been five days *en route*.

As the first special measure of prevention, then, we should give our prompt attention to the protection of the sick individual against the bites of mosquitos. This can best be accomplished by thorough screening, without delay, of the windows and doors of the room occupied by the patient and with as little disturbance as possible, so that any insects already present in the room may be prevented from escaping. As it will not be feasible to make use of any of the destructive agents against mosquitos already within the patient's room until recovery, every precaution should be used to see that the insects do not escape in opening and closing the door. Screens at windows should not, for this reason, be movable. As it is possible that mosquitos that have already bitten the sick individual may have escaped into other apartments of the house, these should be closed tightly and subjected either to sulphur or to formaldehyde disinfection, or

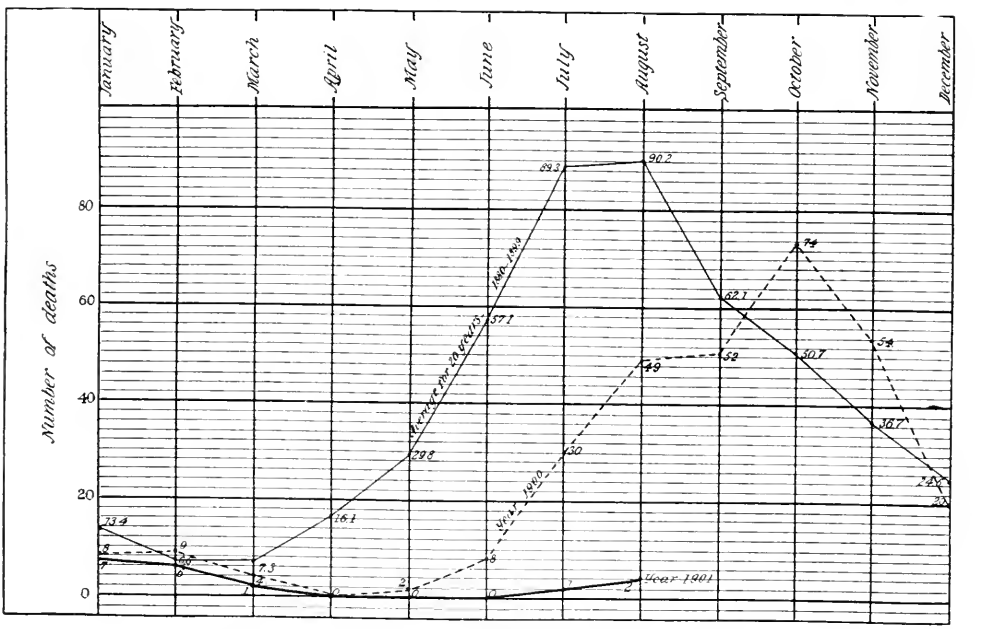

FIG. 10.—Chart Showing Monthly Mortality from Yellow Fever in the City of Havana for the Twenty Years, 1880 to 1899; for the Year 1900, and from January 1 to August 31, 1901.

simple reason, as shown by numerous observations made by us, that mosquitos, when deprived of water, die within a few days. Even if allowed to fill themselves with blood immediately before the experiment is begun, and then deprived of water, practically all are dead by the expiration of the fifth or commencement of the sixth day. We may say that of a large number of insects tried in this way, only one female has survived until the sixth day, and then in a feeble condition. Males and females which have been living on sugar and water, or fed two days before on blood, if deprived of water and food, begin to die after twenty-four hours, and all are dead on the fourth morning. Free access to water, therefore, is necessary for the existence of this mosquito.

Add to the deprivation of water the chances of injury to so frail an insect packed in with articles of clothing, e c., and we see that infected mosquitos to the fumes of burning pyrethrum. According to Dr. Gorgas, the efficient Health Officer of Havana, preference is given to pyrethrum powder, burned in the proportion of one pound to 1,000 cubic feet of air space.[1] He, however, adds: "As the pyrethrum powder, even in this large quantity, does not certainly kill all mosquitos, the room is opened at the end of three hours, and the mosquitos on the floor swept up and burned."

We have mentioned above, in the order of their efficiency, the agents which are most destructive to stegomyia. According to our observations, an exposure for one and a half hours to sulphur fumigation, in a well-closed room, in the proportion of one pound to 1,000 cubic feet of air space, will suffice effectually to destroy all mosquitos. Formalde-

[1] MEDICAL RECORD, New York, Vol. 60, No. 10, September 7, 1901.

hyde gas is not quite so efficient. With Trenner's formaldehyde generator, charged with formalin, 900 c.c.; glycerin, 9 c.c.; methyl alcohol, 360 c.c., which we have found quite reliable for the destruction of bacteria, an exposure of not less than three and preferably four hours is required in order to kill these insects in a tight room having 2,800 cubic feet capacity. Pyrethrum powder, if burned in the proportion of 4 oz. to 1,000 cubic feet of air space, will stupefy all mosquitos at the expiration of one hour, so that they will fall to the floor in a helpless condition. If used, however, the precaution above recommended by Dr. Gorgas should be strictly followed; that is, the room should be opened at the end of three hours, and all insects carefully swept up and burned. The practice of destroying all mosquitos in adjoining houses, as carried out in the city of Havana with such excellent results we consider of the greatest importance, since only in this way can we hope to destroy infected mosquitos, and thus prevent the occurrence of secondary cases. In other words, relying upon the well-known slow progress of the spread of yellow fever, we seek to catch and destroy all mosquitos within a given radius of the first case. If secondary cases should occur, the same hygienic measures should be rigorously enforced along the lines above indicated. Upon the completion of the case, the room occupied by the patient should be disinfected, and in a matter where so much is at stake, we believe that sulphur should be given the preference as a disinfectant. In case of death, the body should be carefully screened against mosquitos, as stegomyia will bite the dead body, and might in this way acquire the parasite.

We have said nothing about the protection of non-immune individuals who enter the patient's room or house, since if the case, under consideration is the infecting case, no danger is incurred. As the duration of the attack is short, generally less than ten days, the patient's room will have been disinfected, and the infected mosquitos destroyed before they have become susceptible of conveying the disease to others. We desire to emphasize the fact that the interval elapsing between the infection of this mosquito by biting a case of yellow fever and the time when it has become capable of conveying the disease, viz. about twelve days, is of the utmost importance in our efforts toward stamping out yellow fever at its very commencement, since it furnishes a non-dangerous interval during which all infected insects should be easily destroyed. It thus makes the control of yellow fever, hereafter, a simpler and more certain matter than the suppression of an outbreak of any of the other acute infectious diseases. If non-immunes entering an infected house desire protection against the bites of stegomyia, this may be obtained by rubbing all exposed surfaces of the body, including the ankle surfaces, with spirits of camphor, oil of pennyroyal, or a 5-per-cent. menthol ointment. The protective effect of these substances is, however, only temporary.

What we have already said concerning the breeding places of *stegomyia fasciata* should sufficiently indicate the general hygienic measures that should be taken in order to prevent the spread of yellow fever. These should consist in enforcing such measures as will effectually destroy the breeding places of this very domestic mosquito. The methods adopted by the Chief Sanitary Officer of Havana, during the present year, may be taken as a model by our sanitary officials.[1] It should not be forgotten that a well-drained and well-sewered city, with a pure water supply and clean streets, has no protection against the spread of yellow fever, provided rain-water barrels and other collections of water are present, in which stegomyia may breed. In one of the forts, on the outskirts of Havana, which was otherwise in an excellent sanitary condition, we found thousands of *stegomyia fasciata* breeding in tin cans placed about the legs of a table in an officer's kitchen. Our conception of yellow fever, therefore, as a "filth" disease must be abandoned, and our attention turned to yellow fever as a mosquito-borne disease. In illustration of what may be accomplished by sanitation based on the latter method of propagation, we present herewith a chart (Fig. 10) showing the actual monthly mortality from yellow fever in Havana, for the period from 1880 to 1899, and also for the years 1900 and 1901. Comparing the mortality from this disease for 1899, which was the most favorable year for yellow fever that Havana had experienced in twenty years, with 1901, during which sanitation, based on the demonstration that yellow fever is propagated by the mosquito, has been enforced, we find a reduction in mortality of 83.3 per cent. in favor of the present epidemic year (April 1 to August 31); or if we compare the mortality for the epidemic year 1900 with the present year we observe a still greater reduction in favor of the latter, viz. 41.1 per cent.

The sanitary regulations put into force February 15, 1901, by Dr. Gorgas, resulted in freeing Havana from yellow fever within three months, so that for a period of fifty-four days—May 7 to July 1—no case occurred. On the latter date, the disease was brought into Havana from Santiago de las Vegas, and, according to Gorgas, has been introduced into the city at least a dozen times from this and other sources. In spite of these new sources of infection, July has only furnished four cases, with one death, and August eight cases, with two deaths. If such admirable results, under new methods of sanitation, have been obtained in this hotbed of yellow fever, we cannot believe that the intelligent and efficient boards of health of our cities will again permit this disease to assume an epidemic form in any city of the United States.

Measures Directed Against the Importation of Yellow Fever Into the United States.—Under the admirable system of inspection and reports, as carried out by the Marine Hospital Service, the appearance of yellow fever at any foreign port is promptly reported for the information of the health authorities of our several Atlantic ports. We may, therefore, divide foreign ports within the so-called epidemic zone into (*a*) infected, and (*b*) non-infected ports. Heretofore, no distinction has been made by the health officers of our Southern ports, as regards quarantine regulations from April 1 to November 1, between infected and non-infected places. All ports within the epidemic zone of yellow fever were considered as being infected places, and hence passengers and vessels were subjected to quarantine and to disinfection of both baggage and cargoes.

With our present knowledge of the way in which yellow fever is propagated, we believe that in the treatment of passengers, as well as of cargoes, a sharp distinction should be made, first, between infected and non-infected ports; and, secondly, in the case of vessels sailing from infected ports, between those that have received their cargoes and passengers in mid-stream and those that have loaded at the wharf.

We believe that no quarantine restrictions should be placed upon either passengers or cargo from non-infected ports. In the case of a vessel loading in mid-stream at an infected port by means of lighters, we believe that she can only receive infection in one way, *i.e.* by passengers who have been exposed

[1] MEDICAL RECORD, New York, Vol. 60, No. 10, September 7, 1901.

yellow fever on shore, and who, coming aboard, may thereafter be seized with the disease. The possibility of infected mosquitos reaching the vessel, either by flight or by means of lighters, may be considered as highly improbable.

Vessels, loaded under the foregoing circumstances (*i.e.* by lighters in mid-stream), and arriving at our ports without yellow fever developed *en route* should have their non-immune passengers quarantined for five days, counting the time consumed by the voyage as part of the quarantine period, and should be allowed to discharge their cargoes without delay. If the disease has developed *en route* among crew or passengers, the sick should be promptly removed; the forecastle or staterooms, as the case may be, thoroughly disinfected with sulphur or formaldehyde gas, and the vessel allowed to proceed to her wharf.

On the other hand, if the vessel has received her cargo at the wharf of an infected port, there is a possibility that she may have received infection in three ways: First, either by contaminated mosquitos that have bitten a case of yellow fever in the immediate vicinity on shore; secondly, by mosquitos that have become infected from biting a yellow-fever patient present on another vessel loading at the same, or at an adjacent, wharf; or, thirdly, by some individual who has acquired the infection on shore and afterward taken passage on the vessel.

In our opinion, however, the chances of infection of a vessel by contaminated mosquitos coming aboard from a house or ship in close proximity are very slight; although such a possibility must be admitted, and the further possibility that recently infected mosquitos may have sought refuge on the vessel during the night preceding her day of departure. It is also possible that a case of mild, and hence undetected, yellow fever may occur on board, and be the source for the infection of mosquitos already present in the vessel.

Under these circumstances, if a sufficient number of days have not elapsed between her port of departure and port of arrival in the United States, *i.e.* sixteen to twenty-one days, to demonstrate the presence of infected mosquitos by the occurrence of a case or cases of yellow fever *en route*, we know of no way of absolutely excluding the possibility of importation of the disease by such a vessel than by the detention of all non-immune passengers for such number of days as will show their freedom from infection, and by careful disinfection of crew's and passengers' quarters.

If more than twenty days have elapsed during the voyage, without the occurrence of yellow fever, we see no good reason why either passengers or vessel should be detained.

We have said nothing about the disinfection of the vessel's cargo, for the reason that we do not consider this to be necessary. The only possible excuse for subjecting the cargo to disinfection would be the fear of the presence of infected mosquitos in the vessel's hold, provided she had loaded at the wharf of an infected port. In this instance, if the voyage has consumed five or more days, all mosquitos contained in the hold will have died; for, as we have already pointed out, *stegomyia fasciata* lives only a few days if deprived of water. We cannot too strongly insist that the danger of importation of yellow fever into the United States lies, not in cargo or personal baggage, but in the individual sick with that disease. With our present knowledge of its propagation, personal baggage should no longer be subjected to disinfection, and, with our increased ability to prevent its spread by measures easy of application, instances should be few and exceptional when a vessel coming from a yellow-fever port should be delayed longer than will be necessary to remove her non-immune passengers who have not yet completed their period of five days since leaving the port of departure.

The chief duty of quarantine officers hereafter will consist in the detection of mild or very mild cases of yellow fever. In a series of twelve cases of experimental yellow fever produced by the bite of *stegomyia fasciata*, we have, elsewhere,[1] pointed out that four, or 33 per cent., were mild or very mild in character, and have indicated the difficulty of making a positive diagnosis in such cases.

In discussing the period of incubation of experimental yellow fever, we have shown that in 16.6 per cent. of our cases the period of incubation exceeded the usual quarantine period of five days. If we add Carter's cases to those observed by ourselves, we find that of twenty-four cases the period of incubation exceeded five days in three, or 12.5 per cent.

We can thus readily see what great danger heretofore lay in the passage through quarantine of just such mild cases, or of those having an incubation stage of more than five days.

While the exclusion of such cases is of the greatest importance, we doubt whether, with our improved knowledge of how to prevent the spread of yellow fever, it would be advisable to place a greater burden upon ships' passengers by extending the quarantine period to more than five days. It appears to us rather that in view of the troublesome delays to which passengers and vessels from yellow-fever ports have been subjected in the past, the time has now arrived, when, standing upon more solid ground, we will be justified in seeking in every way to lessen, as much as possible, the restrictions placed by present quarantine regulations upon the ship's cargo, while we add nothing to those of the passenger.

To this end a most important part will have been accomplished if we can persuade the sanitary authorities of our sister republic, Mexico, and of the Central and South American States, to join us in the adoption of more enlightened methods for the suppression of this widely prevalent epidemic.

ON THE MODE OF TRANSMISSION OF THE INFECTIOUS AGENT IN YELLOW FEVER AND ITS BEARING UPON QUARANTINE REGULATIONS.*

By A. H. DOTY, M.D.,
HEALTH OFFICER, PORT OF NEW YORK.

THE stimulus given to bacteriological research and scientific investigation during the past twenty years has led to many discoveries regarding the means by which infectious diseases are transmitted. The evidence presented is indisputable, although in many instances it is at variance with our former theories regarding this subject.

The recent experiments in Havana under the direction of Dr. Walter Reed, U. S. A., and his colleagues, have conclusively shown that the infectious agent in yellow fever is transmitted by the mosquito, and there is reason to believe that this is the only means by which the disease is propagated. Therefore, it is fitting at this time that we should consider in connection with the above experiments the practical experience of those who have dealt with this disease, in order that we may come to some definite conclu-

[1] "Experimental Yellow Fever," Transactions of the Association of American Physicians, Vol. XVI., 1901.

*Read at the meeting of the American Public Health Association, held in Buffalo, September 18, 1901.

sion regarding the future control of yellow fever and the necessary sanitary procedure in the case of persons and vessels arriving from infected areas or ports. The extent to which commerce has been crippled by what we now believe to be unduly vigorous quarantine regulations can hardly be overestimated, and it is but proper and just that we should take prompt action to give such relief in this direction as is consistent with public health.

The history of yellow fever in the United States and elsewhere has shown that it is usually confined to geographical limits, and that sections beyond these are as a rule free from the disease, although it has occasionally appeared outside of the yellow-fever zone. For instance, between the years 1798 and 1805, many cases of yellow fever occurred in New York, first appearing at the lower end of the city in the vicinity of Peck Slip. Medical history indicates that the disease had shown itself here before that time, but it was not until the period I refer to that it was fully recognized and studied. I have been fortunate enough to secure a copy of the official medical statements relative to these outbreaks, and the opinions which are expressed are in such harmony with the conclusion of modern sanitarians that I submit the following extracts:

Dr. James Hardie, who in 1822 published an official account of these outbreaks, says in reference to cases of yellow fever at Bellevue Hospital in 1798:

"There is one thing very remarkable, with respect to the attendants of this hospital, which ought not to be omitted. Their situation, to most people, must have, no doubt, appeared peculiarly dangerous, as they were literally surrounded by pestilence. It so happened, however, that neither physicians, nurses, nor washerwomen caught the infection. The boatmen, too, belonging to the Health Office, who enter the hospital at all times, and were not only engaged in bringing the sick from the city and shipping, but, likewise, in removing them from place to place, enjoyed a uniform state of good health; and of those persons who accompanied their friends and relations, stayed with them, and nursed them, there is not a single instance of an individual being infected. In short, Dr. Douglas, one of the assistant physicians, was the only person, residing there, who was seized with fever; but he had been in the habit of occasionally visiting his friends in the city, and three days previous to his being taken ill had slept in a house the vicinity of which was highly infected, and it is more than probable that his sickness was occasioned by that cause."

The following extract is taken from the official report of the resident physician at the Marine Hospital on Staten Island regarding the outbreak of yellow fever in 1799:

"During the months of July, August, and October (1799), there were in all about two hundred and fifty (250) persons sick of yellow fever in the Marine Hospital, a great part of whom were from the shipping; the rest from the city. At that time, there were of physicians, nurses, washerwomen, boatmen, and my family, composed of myself, my wife, and three children, thirty-seven (37) persons, not one of whom, although daily and hourly amongst the sick, experienced the least indisposition."

From the official communication addressed to Governor Lewis, January 12, 1806, by Dr. Edward Miller, resident physician of Bellevue Hospital, I quote the following:

"No communication of the disease was ever observed in yellow-fever hospitals, situated at a distance from the cities to which they belong. No exception to this has ever occurred in any of the numerous seasons of this pestilence, at our hospital, at Bellevue, the Marine Hospital on Staten Island, that of Philadelphia, or any other in the United States, provided the malignant air of the city had been avoided. The force of this fact seems never to have been duly considered or appreciated. The numerous retinue of medical attendants, nurses, washerwomen, servants, etc., which belong to our hospitals, must be known to everybody. How greatly they are exposed to contagion, if it could be supposed to exist in this case, is equally known. The most malignant cases of the disease are constantly found in these institutions. The exposure of physicians and their assistants is well understood. The duty of the nurses leads to an incessant and unreserved intercourse with the sick; they sleep and pass the greater part of their time in the apartments of the sick, the dying, and the dead.

"The nurses at Bellevue Hospital became so entirely free from all apprehensions of the contagiousness of this disease that they often slept on the same bed with the sick, and it happened more than once, in the course of the season, that a nurse, overcome with fatigue and want of sleep, threw herself in the night, for a little repose, on the bed of a dying patient and continued there asleep until the patient was dead, and it became necessary to remove the corpse."

The official reports from which I have just quoted contain many statements similar to the above.

Fifty years after these statements were made, a most notable congregation of sanitarians took place in New York City (1859) under the name of the Third National Convention. After a most careful and exhaustive discussion of yellow fever, the following resolution was passed by a vote of eighty-five yeas to six nays:

"*Resolved*, That in the absence of any evidence establishing the conclusion that yellow fever has ever been conveyed by one person to another, it is the opinion of this convention that the personal quarantine of cases of yellow fever may be safely abolished provided that fomites of every kind be rigidly restricted."

To what I have presented above, I shall add my personal experience with this disease, and with persons and vessels arriving from yellow-fever-infected ports. This experience, which covers a number of years, is in full accord with the previous records of the New York Quarantine Station. Its special importance lies in the fact that probably more than one-half of all foreign vessels coming to the United States reach the port of New York, which is in daily communication with yellow-fever ports.

For the purpose of better studying the statistics which I am about to present, it will be necessary to divide the vessels arriving from yellow-fever ports into two classes: (1) Those which are a week or less in transit, such as vessels from Cuban, Mexican, and Central American ports, and (2) vessels coming from ports far away, as Santos and Rio Janeiro (Brazil), which are three weeks or longer in passage. In the first class are found the greater number of vessels, and those with which we come in daily contact. These include both passenger and freight boats. The vessels from Havana, the most numerous, and on which we have heretofore found a large percentage of the yellow fever reaching this port, are from three to five days in transit, while at Havana they do not, as a rule, approach the docks, but discharge and receive their passengers and cargoes in the open bay. A still further restriction has been made. I have recommended that the crews of these vessels be detained on board and not allowed to go ashore. Some of the fast mail steamship lines carrying passengers have made this a rule of the company, and have required its strict enforcement. Vessels from Mexican

and Central American ports, which are included in the first class, are about one week in transit to New York.

The patients with yellow fever removed from these vessels have in every instance been taken sick within five days from the time of departure from the infected port; a large percentage of them showed the first symptoms of the disease during the first forty-eight hours, and some have stated that they were not feeling well at the time of embarkation. As a rule, these cases were found among the second cabin or steerage passengers, and although there was free exposure, in no instance has a secondary case ever occurred. I want to emphasize my statement regarding the exposure, as in the cases referred to it was practically unlimited. Sometimes the disease was not recognized, and the patient remained in the same apartment with others during the entire voyage; at other times, although the patient may have been removed to other quarters, fellow passengers or members of the crew were detailed to care for him, as these vessels do not, as a rule, carry surgeons. The exposure was not only to the patient, but to his clothing, bedding, and discharges also. In instances where a member of the ship's crew contracted yellow fever, it was found that the patient had been ashore, but in no case, so far as I know, has the disease ever occurred among crews which have been kept on board vessels anchored in the bay of Havana. I have no reason to believe that members of the crews of Colon vessels are kept on board during the time that they are in that port; however, I am aware of no case which has occurred among them. This is easily explained by the fact that Colon, in recent years, has been free from yellow fever, and cases of this disease which vessels from Colon bring to the United States are from Panama, about thirty-five miles distant on the opposite side of the isthmus.

Vessels coming from Rio de Janeiro and Santos may be taken as examples of the second class, which are long in transit. These ports are notorious for the prevalence of yellow fever, the bills of health having frequently shown the existence of 400 to 500 cases at one time. Some of the vessels from these ports carry passengers and have medical officers—the majority, however, do not. It is not uncommon for the captain or surgeon to report that, while at Santos or Rio de Janeiro, or within two or three days after leaving, a passenger or member of the crew became sick with symptoms clearly indicating yellow fever, and either died and was buried in port or at sea, or recovered. Their report also shows that in no instance were these followed by secondary cases after the boat had been five days at sea, although there was full exposure and no disinfection. But in no instance has a case of yellow fever been found on a vessel reaching here from these ports. This can easily be accounted for, as all who had yellow fever on these vessels were taken sick at Santos or Rio de Janeiro, or within three or four days from departure, and either died or recovered long before the vessel reached this port, the voyage taking about twenty-one days; whereas cases occurring on vessels of the first class reach here during the active stages of the disease. Neither have secondary cases ever occurred among those connected with the Swinburne Island Hospital in New York Bay, to which place all persons suffering with yellow fever are transferred from incoming vessels.

A careful analysis of these statistics clearly shows that secondary cases have not occurred as the result of exposure to those who have contracted yellow fever in the infected area, or to their clothing, bedding, etc., and that when persons have reached New York and are well after having been five days or more from the port of departure, they have not afterward developed the disease. Inasmuch as passengers and crews arriving on incoming vessels which have yellow fever on board are not detained at this station if they are well and have been five days from a yellow-fever-infected area, it is naturally asked, how can I be certain that mild cases, at least, may not develop after they have left my jurisdiction? My answer is this: First.—If secondary cases occurred as the result of personal contagion, or exposure to clothing, bedding, etc., there would be many of them, as there is full exposure; furthermore, cases occurring as the result of this exposure would not all be mild, and some would surely present themselves in a typical and fatal type. If this occurred in New York City, or elsewhere, it would be known and the disease traced to its origin. Second.—Those who are removed at this port sick with yellow fever are, as a rule, second-class or steerage passengers, and their apartments are on the same deck and in constant communication with the crew of the vessel, and entirely separate from the cabin passengers, who are on the deck above. Therefore the exposure is largely confined to the crew, who are frequently in close contact with the patient; moreover, members of the crew are often detailed to look after those sick with this disease, and in this way freely handle the clothing, bedding, etc. The crews of the vessels upon which the cases are usually found are, as a rule, permanently employed by the companies, and although they visit their home while the vessel is in this port, they return again to the ship before sailing. If they were confined to their homes with yellow fever, or any disease resembling it, or were taken sick in transit to Havana, it would sooner or later be brought to my attention. Third.—We have the experience of sanitarians during many years past to show that yellow fever is not transmitted by personal contagion, or by exposure to the clothing, bedding, etc., of those sick with this disease.

When we study the practical experience which I have just presented and which comes to us from different periods during the past century, we can reach but one conclusion, *i. e.* that yellow fever is not contracted by personal contagion. This, however, is not by any means all that it shows, as the same evidence just as clearly proves that the clothing, bedding, discharges, etc., are not media of infection. In Dr. Miller's communication to Governor Lewis and in Dr. Hardie's hospital report, cited above, as well as the experience which I have presented, specific reference has been made to the full exposure in the hospital, on shipboard, etc. If those who are in constant attendance upon persons suffering from yellow fever and are in close and prolonged contact with their clothing, bedding, discharges, etc., at all times and under all circumstances, are not infected through the medium of this material, when does it transmit infection? Both Dr. Miller and Dr. Hardie refer particularly to the exposure of washerwomen—they unquestionably mean through the medium of the linen, bedding, etc., of the sick. This could not have been previously disinfected, as at that period such treatment was not carried out, and there is every reason to believe that these helpers received the bed linen, clothing, etc., direct from the patient, often contaminated with vomited matter and other discharges, both dry and moist, and the records show that in no instance did secondary cases occur. The opinion of these early observers, which represents their personal experience, is of inestimable value, as they were meeting this disease for the first time, and it is reasonable to suppose that they had formed no previous ideas regarding the means by which yellow fever is transmitted. In order to make these views acceptable

from a practical standpoint, it has been necessary to show in what way, other than through the affected person, or his clothing, bedding, etc., yellow fever is transmitted. It would seem that the experiments of Dr. Reed have furnished this information, inasmuch as the result of his work conclusively shows that the disease is transmitted by the mosquito and not by clothing, bedding, etc. This may be regarded as a confirmation of our practical experience.

To those who have had but little practical experience in this matter, or those who live within the yellow-fever zone, where extreme measures have been regarded as necessary to prevent the appearance or extension of yellow fever, this view carries with it such a complete and abrupt change in the treatment of yellow fever, as well as the treatment of persons and vessels arriving from yellow-fever ports, that it can hardly receive unbiased consideration.

The opposing views regarding the means by which yellow fever is transmitted may briefly be summed up as follows: On the one hand, we have conclusive evidence, as the result of practical experience and scientific investigation, that yellow fever is not contracted by personal contagion, nor by the clothing, bedding, discharges, etc., of persons suffering with this disease; furthermore, there is positive proof that yellow fever is transmitted through the medium of the mosquito. On the other hand, those who hold that the disease is transmitted either by personal contagion or by the clothing, bedding, etc., of the sick, have had but little to support their theory aside from the fact that the true cause of infection was unknown. The result of the Havana experiments leaves now but little justification for this belief.

I am well aware that from time to time evidence has been presented, which is intended to show conclusively that yellow fever is contracted by personal contagion, or through the medium of clothing, bedding, etc. In considering this, we must bear in mind that heretofore we have had no positive evidence as to the means by which yellow fever is propagated, and all have been free to form their own ideas regarding this subject, and very naturally persons, or clothing, bedding, etc., have been accepted as the medium of infection. However, I believe that it is pertinent to ask if, in the instances just referred to, the presence of the infected mosquito would not afford a full explanation for the appearance of the disease. Furthermore, we do not fully appreciate the danger from mild or unrecognized cases as the cause of outbreaks, not only of yellow fever, but also of other infectious diseases, nor is it fully understood how frequently such mild cases occur. Again, we do not consider the errors in diagnosis which may occur, even on the part of the best diagnosticians. Unconsciously, we are very apt, after having accepted a theory, to entertain only such evidence as tends to strengthen our belief in that direction. How can we reasonably entertain a statement that yellow fever follows the exposure to some garment, or other material, when we have such indisputable evidence as I have presented to show that the disease is neither contracted by personal contagion nor by the clothing, bedding, etc.? The hospital reports of 1798 to 1805, to which I have referred, are invaluable, as at that time disinfection was not understood, and there is not the slightest evidence that any protection was afforded in this manner. Furthermore, I am unable to find any reliable or conclusive evidence to show that in the outbreaks of yellow fever, which from time to time have occurred in the South, disinfection has been of any value in abating the disease. In connection with this, I will call attention to the fact that, in the experiments made by Dr. Reed, non-immunes were placed in prolonged contact with the bedding, clothing, etc., of those sick with yellow fever without the slightest evidence of infection; and is it not significant that those living within the yellow-fever zone have learned to look forward to the appearance of frost, the period which terminates the activity of the mosquito, as the only prompt and sure means of ridding a community of yellow fever?

If we accept a sanitary science, we must abide by its teachings, and I know of no better time than the present to look this matter fairly and squarely in the face, and make such changes in our sanitary regulations as are necessary to conform to our present knowledge of yellow fever. What I am now advocating I put into practical operation five years ago, at the port of New York, as, after a careful consideration of the subject, I was convinced that yellow fever is contracted neither by personal contagion, nor by the clothing, bedding, etc., of those suffering with this disease. Since the time stated above, many vessels have arrived here with persons sick with yellow fever, and with the bodies of those who have died of the disease during the voyage; but in no instance have those on board been detained if they are found to be well, and if five days have elapsed since the departure of the vessel from the infected port, although there may have been free exposure to the patient, his clothing, bedding, etc.; however, no secondary cases have ever occurred. It is true that, after the removal of the patient, disinfection is performed in compliance with existing quarantine regulations; but this treatment on the arrival of the vessel can in no way affect those who had been in close contact with the patient while *en route*. I believe the value of Dr. Reed's experiments lies largely in the fact that they indicate a line of procedure in the treatment of yellow fever which, if promptly and properly carried out, limits at once the extension of the disease. I refer to the use of netting, and other means, to guard against the mosquito. Commerce has patiently suffered the enforcement of regulations which, in the present light of our knowledge, are uncalled for, and it is but just that we should give this subject prompt consideration.

There are some details regarding the relation between the mosquito and yellow fever which are yet to be made clear; for instance, why do not infected mosquitos reach vessels lying in Havana harbor, not far from the shore, or vessels which lie at the dock at Santos and other infected ports, and at some subsequent time, or at different periods, transmit the disease to those on board, or at the point of destination? Yellow fever does sometimes occur among the crews of vessels docked at yellow-fever ports, but this is easily explained by the fact that the crews are allowed to enter the town. In explanation of this it may be said that all who have studied the habits of the mosquito fully agree that it prefers to remain in the immediate vicinity of its breeding or abiding place; this is also borne out by the fact that we do not see secondary cases of yellow fever on shipboard, provided the vessel has left the infected port, and there is but little reliable evidence that infected mosquitos are transmitted to foreign shores. It is not impossible for this to take place, and instances have been reported where secondary cases have occurred after leaving port. How many of these statements are authentic, I do not know; but of this I am sure, that it occurs only in rare instances, and we are surely not justified in making our rules conform to these possible exceptions. Suppose that it should be deemed necessary to take action against this possible danger, what can be done that is reasonable? We cannot assume that the mosquito is confined to any special part of the ship; it may be in the

forecastle, saloon, engine room, or in the hold of the vessel. Therefore, if we are consistent in carrying out such an extreme measure, we cannot stop short of fumigating or in some other manner treating every part of the ship. To those who are familiar with this work, I need say nothing; to those who have never undertaken it, I say that such treatment is the most formidable and expensive that a quarantine officer is called upon to perform, besides the long delay to the vessel. Moreover, such action is justifiable unless there is satisfactory evidence that infected mosquitos are on board, as would be indicated by the appearance of secondary cases of yellow fever after a departure of five days from an infected port.

Another question may here be presented for consideration, and it is this: Does five days represent the maximum period of incubation of yellow fever, or may the disease develop after a longer period of time? I am aware that instances have been cited where the disease has occurred after a period of incubation of six or seven days, or even longer, but none have come under my notice. I believe the early symptoms generally present themselves on the third or fourth day. There is no doubt that errors are often made in computing the period of incubation, as persons may be passing through the early stage without any well-marked evidence of it. This I have detected a number of times by the use of the clinical thermometer. A reference to the opinion of many careful investigators, among whom we find Dr. George M. Sternberg, will show that it is the general opinion that five days is the maximum period of incubation. I believe this is sensible and safe, and that regulations should be made accordingly, notwithstanding the fact that evidence has been presented which tends to show that it occasionally covers a longer period.

If we believe that yellow fever is not transmitted by personal contagion or by the clothing, bedding, etc., of those sick with this disease, and that the medium of infection is the mosquito, we must admit that disinfection offers but little protection. No other view is reasonable or logical. Our efforts, therefore, should be turned toward the detection of cases of yellow fever and their treatment according to our present knowledge of the disease. There is no doubt that many outbreaks of yellow fever have been caused by the presence of mild or unrecognized cases where the infection was attributed to clothing, etc. For this reason special effort should be made to detect this type of the disease, which can be done only by a careful and thorough inspection. Moreover, each community which is liable to be visited by yellow fever should be provided with means for the special care of yellow-fever patients, where the most approved methods of protection against the mosquito are in operation. Furthermore, health officials should be familiar with the different varieties of mosquitos, and should, from time to time, make investigations to ascertain, if possible, the presence of the insects which transmit infectious material. I cannot agree with those who hold that a bad sanitary condition does not constitute an important factor in the propagation of either yellow fever or malaria. I am satisfied that it does, inasmuch as filth and bad drainage furnish the breeding places for the mosquito.

In accordance with the above views, the treatment of incoming vessels from ports infected with yellow fever becomes very simple: if they are five days or more in transit, and all on board are found to be well after a careful inspection and the use of the clinical thermometer, the vessel, its passengers, and crew shall be released without further detention or treatment. If the vessel has been less than five days in transit, all on board who cannot present satisfactory evidence of immunity should be removed and held for observation until the completion of a period of five days from the time of departure from the infected port, and then released only after a careful inspection. When yellow fever is found on incoming vessels, the procedure should differ only so far as it concerns the removal of the patient to a properly constructed hospital or apartment for treatment.

Dr. Reed's experiments have not conclusively shown that there may not be some other means than the mosquito by which yellow fever is transmitted. But when these experiments are considered in connection with the results of our practical experience, it is clearly evident that this disease is not contracted by personal contagion or through the medium of clothing, bedding, cargoes of vessels, etc. Therefore I believe we are justified in changing our quarantine regulations to conform to these views, and that such a proceeding is safe and reasonable, particularly as we now have at hand a method which, if properly and scientifically carried out, can be depended upon to limit the extension of yellow fever. If the future shows that there are other means of infection, it will then be time enough to add whatever restrictions are necessary for the protection of the public health.

I am convinced that in following this line of action we are not only offering full protection to the public, but are extending to commerce a relief from unnecessary and unreasonable regulations.

ARTERIO-SCLEROSIS: IMPORTANCE, DEFINITION, ETIOLOGY, AND SYMPTOMATOLOGY.*

By CHARLES E. NAMMACK, M.D.,

PROFESSOR OF CLINICAL MEDICINE, CORNELL UNIVERSITY MEDICAL COLLEGE; VISITING PHYSICIAN TO BELLEVUE HOSPITAL, NEW YORK; ATTENDING PHYSICIAN FOR OUT-PATIENTS, NEW YORK HOSPITAL.

Importance.—To appreciate properly the importance of arterio-sclerosis, we must begin by divesting ourselves of the idea that the blood vessels are mere tubes for the conduction of the blood. They are not mere appendages of the heart, but the heart is rather an appendix to the blood vessels, for low in the scale of life the circulation is carried on without a heart. The study of the blood vessels is the study of the ultimate processes of life, for not only have they the mechanical functions of contraction and dilatation, but they have also the living functions of oxygenation, nutrition, and all of that wonderful and little understood group of changes which are classified as metabolism. Nature, as yet, works here in her secret laboratory, and we must perforce be content with the study of changes visible to the eye.

The time when pathological changes begin in the vascular walls of an individual marks for him the beginning of his decline and decay, irrespective of his length of years. One man may be old at thirty, another young at fifty, and the time of one's death may be precipitated by causes which accelerate or intensify these pathological changes. So many of these causes enter into the lives of working physicians that the importance of a careful study of this subject is manifest, that our own days may be long in the land.

It will be recalled that the walls of the vessels are three in number. The outer wall, chiefly fibrous, carries the nutrient vessels and gives strength to the structure. The middle wall is muscular and elastic; it receives the nerve supply, and is the essential factor in the regulation of the circulation and the distribution of the blood. The inner wall is a layer of apposed flat cells, endowed with a peculiar kind of osmotic function which ministers to metabolism and

* Read at the eighteenth annual meeting of the New York State Medical Association at New York, October 23, 1901.

forms part of the phenomena of life in the capillary vessels.

The influence of the nervous system is shown in its driving power, not only on the heart, but also on the vessels themselves, in whose muscular walls there are "local hearts;" and these local hearts regulate local pressure, and have, moreover, immediate connection with the central heart. External influences, such as cold, heat, abdominal massage, and hydriatic methods, also influence very markedly the smallest vessels. The vaso-motor center has been located in the medulla, but the influence of the cerebrum itself is shown in the phenomena of blushing, pallor, and the anomalous circulatory changes of hysteria. Pathological conditions influencing the vessels are many and varied. Bright's disease causes hypertrophy of the heart by irritation of the vaso-constrictors by the excrementitious substances accumulating in the blood in consequence of defective renal excretion. Hysteria causes marked and sudden changes by an abnormal mechanical irritability of the cutaneous vessels, as seen in dermographism, blue œdema, subcutaneous hemorrhages, and the free hemorrhages corresponding to the wounds of Christ.

All this change does not depend upon muscular contraction and dilatation. Much of it is caused by the action of the cells which compose the walls of the capillaries; this shows that the blood vessels are not inert tubes, but highly differentiated organs doing part of the work of life. With this preliminary understanding, we may consider that pathological state known as arterio-sclerosis, or, more correctly, as arterio-capillary fibrosis, the name originally given it by Gull & Sutton in 1872.

Definition.—Arterio-sclerosis is a hyaline degeneration of the structural elements of the arterial wall, with connective-tissue substitution, hyperplasia, and subsequent contraction with induration, whereby the characteristic functions of the vessel wall, retention, absorption, metabolism, with the power of expansion and contraction, are weakened and lost. The hyaline process is usually associated with atheromatous and often with chalky and fatty changes. Atheroma may be regarded as the physiological form of thickening of the arterial wall, and arterio-sclerosis the pathological; but arterio-sclerosis may exist without atheroma, and atheroma without arterio-sclerosis, though frequently both are manifested in the same subject. Whether the first change begins in the blood, or in the blood-vessel wall, or in the nervous system, cannot be determined as yet; but the tendency of modern opinion is to locate the origin of arterio-sclerosis in the blood.

The first effect of arterio-sclerosis shows itself in the impairment of contractility, later in weakening of elasticity and osmosis, and consequent interference with metabolism.; next, in the escape of fluid, constituting the various dropsies, and the exudation of albumin from the walls of the vessels of the Malpighian bodies; finally, in the failing nutrition, emaciation, and marasmus which mark the terminal stage. The increased resistance in the vessels throws extra work upon the heart, which first hypertrophies and then dilates. But if the heart continues strong and the vessel grows weak, we may have distention of the vessel wall (giving aneurysm) or rupture, causing apoplexy. Thus the arterial system, which leads the van in the development of the body, is also that upon which the finger of decay is earliest laid. The assault of death begins at the circumference and ends at the center, and though we cannot prevent the sapping of the outworks, we can reinforce the citadel, and thus we are often able to postpone the ultimate surrender. But it is sometimes impossible to foretell whether the enemy will first storm the heart, the kidneys, or the brain.

Etiology.—The causes of this condition may be considered under the headings of heredity, age, sex, alcohol, syphilis, gout, rheumatism, certain acute infections, high living, and hard work. In Osler's terse English, the onset may be said to depend, in the first place, upon the quality of arterial tissue (vital rubber) which the individual has inherited, and secondly, upon the wear and tear to which he has subjected it.

Age is a very indefinite expression. That a man is as old as his arteries may be a trite saying, but it is true. It is failing arterial nutrition that produces advancing age, and cuts off most men's chances of reaching a century of existence. The habits largely influence the production of arterio-sclerosis, however, and give to lives of self-denial or of self-indulgence their corresponding reward of longevity or punishment of short life. Of course, the gross alteration of atheroma is undoubtedly a disease chiefly of middle and advanced life, but the finer changes of arterio-sclerosis may be determined much sooner, even in childhood and early youth. In fact, there is no doubt that individuals are born differing in the thickness and strength of arterial walls, as much as in structure of other organs. Since men are more frequently affected with alcoholism, syphilis, gout, etc., and are subject to more mental and physical strain than women, it follows that the preponderance of cases occurs in the male sex.

Alcohol acts in many ways to bring about arterial degeneration. First, it over-excites the heart, so that the vessels are subjected to greater strain; second, it disturbs digestion, causes liver cirrhosis and kidney insufficiency which load the blood with poisons; third, alcohol is itself a poison to the blood.

Syphilis causes so much thickening of the inner wall of the vessels as to lead to great diminution, or final obliteration, of their caliber. It may also deposit gummatous nodules in the outer wall. Syphilitic changes seem to show a predilection for the brain arteries, especially for the brain that has been weakened by other injurious influences, and sometimes produce, besides the endarteritis obliterans, a circumscribed granulation tumor (syphiloma) in the walls of arteries and veins. Syphilis attacks the brain vessels by preference because syphilitic arteritis is localized in arteries supplied with lymphatic sheaths

Certain acute infectious diseases, especially typhoid fever, malaria, influenza, scarlet fever, and diphtheria, may lead to arterio-sclerosis, either by injuring the vaso-motor nerves, and thus leading to changes in the vessel walls, or by directly affecting the endothelium by their specific micro-organisms or toxins.

Chronic diseases, like gout, rheumatism, saturnism, and diabetes, are frequently attended by arterio-sclerosis or atheromatous changes in the vessels. Toxins, like ergot and lead, produce protracted spasmodic contraction of the smallest vessels, whereby the blood pressure is increased and extra work thrown upon the heart and large vessels.

Overfeeding and drinking induce a simple plethora of the vessels, but, in addition, load the blood with toxins in the case of high livers with sedentary habits. Yet, as an initiative, there must be peripheral obstruction to produce hypertrophy of the heart, because Strasburg geese may be stuffed to repletion to supply the market with *foie gras*, or young porkers fattened for the butcher, without producing cardiac enlargement. Hard work acts by raising the blood pressure and subjecting the heart to hypertrophy and the vessels to strain. This is especially true if the work be accompanied by depressing psychical emotions, or accomplished under circumstances of pro-

longed mental and physical strain. The labor we delight in pains, yet who has not felt the increase of his arterial tension and the booming of his heart when, after a long night's vigil by the bedside of a parturient primipara, the time had arrived to assist Nature's failing efforts. It is not work, but worry, which leads to premature senescence. Yet, how little the public credits us with worry about our work! How many believe that men become but specimens in our eyes, and that there is no room left in us for ministry to the agony of hearts whose only disease is grief! Yet who has not seen some great leader of our profession, whom forty years of hard practice has not yet hardened, with moistened eyes and blanched cheek, forcing himself to say that for some beloved relative science had no remedy. Sleepless nights and anxious days, hours of tense apprehension, the exertion of almost superhuman ingenuity to relieve pain, are alike the portion of our rural William MacLure's and of our city brethren. Few, indeed, have the opportunities, few also have the cares and strain of a good physician who is also a good man. And arterio-sclerosis, the cause, not the effect, of advancing age, finds its root in these. The death rate of medical men in New York and Brooklyn, from 1884 to 1892, was exceeded only by that of saloonkeepers who are intemperate by that of butchers who are gluttonous, by that of quarrymen who are exposed to the dangers of explosives, and by that of the most underpaid of factory operatives. And of those who died, 35 per cent., or more than one-third, died from the threefold sequela of arterio-sclerosis, that is, from Bright's disease, apoplexy, and heart disease. As against this showing, the death rate from these causes was only 25 per cent. among all the male adults in New York City, including all the tramps, vagabonds, and drunkards who drift into the city to die. Arterio-sclerosis, then, is preëminently the doctors' disease.

Symptomatology.—The clinical history of arterio-sclerosis is not the mere story of the past few weeks, but comprises the life history of the patient from his cradle, and often includes that of his forefathers also. The symptomatology sometimes makes its diagnosis easy and certain, sometimes only presumptive, sometimes impossible. The disease may be extensive and show no external signs whatever. Or it may be distinctly indicated by the hardness and serpentine course of a radial, temporal, or other accessible artery. Latent arterio-sclerosis may require for its detection an increase in the blood pressure discernable only by instruments of precision, like the sphygmometer, arteriometer, or the sphygmograph. The disease may be latent for a long time, and the symptoms which eventually appear will depend upon the organ which is most affected. Thus, when the aorta suffers, we may have aneurysm with its accompanying train of symptoms. When the coronary arteries are implicated, we have heart failure, arrhythmia, and stenocardia. Affection of the bronchial and intercostal arteries may give weak respiratory efforts, defective expansion of the chest, emphysema of the lungs. When the process is general (arterio-capillary fibrosis of Gull & Sutton) or when it involves large organs, and by increasing blood pressure throws extra work upon the heart, we have hypertrophy of that organ, giving place later to dilatation, each condition giving its characteristic symptomatology.

Sclerosis of the coronary artery announces itself by palpitation after meals, dyspnœa after slight effort, oppression over the upper part of the sternum, or a sharp pain in the left arm, which is at first relieved by cessation of muscular effort. Later on, attacks of true angina pectoris may set in. Arterio-sclerosis produces nowhere more serious change than in the kidney, leading to cirrhosis with its classical signs, to wit: abundant urine of low specific gravity, little albumin, hypertrophied heart. Brain symptoms at first require keen observation, or rather keen perception, on the part of the patient himself. Earlier fatigue, disinclination to effort, especially to the physical effort which has perhaps made the man successful in life, irritability, alteration of disposition, headaches in crowded assemblies or in the study, headache after the very moderate use of alcohol, tobacco, or coffee, all indicate the point where the habits of life must be revised and corrected, where the individual must take in sail. The city doctor of forty years of age must consider selling his horse, abandoning his dinner glass of wine, cigar, or coffee, and spending more time in the open air. His summer vacation must be longer, and must be spent in some place where he will firmly decline to infringe upon the practice of the local practitioner. The pursuit of the elusive golf ball may be taken up in lieu of the still more elusive pursuit of fame and wealth. Outdoor air expands arteries better than iodides do. Night work, if possible, must be handed over to some younger man with more elastic arteries. It is by securing these advantages and turning them to the good that vital decline is arrested and chronic ailments remedied when that is possible, rather than by the unguents, the hot baths, and the elixir vitæ, by which our forefathers sought to emolliate the rigidity of age, and to add a fresh stock of vital force to that which was fast wearing away.

Herbert Spencer's definition of life, *i. e.* that it is "the continuous adjustment of internal relations to external relations," while not answering all the problems of our inquiring reason, is yet practically sufficient for the physician who deals only with the physics involved in life.

By adopting these measures, one affected may hope to escape the advanced brain symptoms of the process. These are, weakening of the mental faculties, vertigo, insomnia, transitory speech-disturbances, mental disturbances, melancholia, irascibility of temper, or perhaps an abrupt closure of the scene with apoplexy.

In the vessels of the extremities, coldness of the surface, rheumatoid pains on walking a short distance; later, changes in the color of the skin and perhaps gangrene may be observed. Raynaud's disease is sometimes referred to this cause.

I have endeavored to present here, concisely, what is given in the writings of the authors, references to which are hereto attached; but I am indebted chiefly, almost wholly, to the comprehensive article by James T. Whittaker.

CINCHONISM AND ITS EFFECT UPON ARTICULATION AND VOCALIZATION.*

By CARL SEILER, M.D.,
SCRANTON, PA.

It is by no means my intention to enter into a detailed and lengthy dissertation upon the apparently impossible relation between subjective audition and sound emission, as such an attempt, even in its merest outline, would carry me far beyond, not only the legitimate time for a paper, but even beyond the limit of laryngology and otology, and land me in the as yet unexplored vastnesses of what for want of a better name might be called psycho-physiological physics.

All I wish to bring before the society is a summary of the deductions and quasi conclusions which I have arrived at from a large number of observations, including the tests made on myself and my own personal experiences, of the effect of tinnitus aurium, the aural symptoms of what is generally termed cinchonism, as well as of external, non-subjective noises, upon vocalization and particularly upon articulation, most prominently noticed by the subjects in the pronunciation of certain of the consonants. That it was no easy matter to get definite data in regard to the loudness and pitch of the subjective aural sensations in the majority of cases can be readily appreciated, and also that the difficulty was greatly augmented when it became necessary to determine the loudness and pitch of the external non-subjective noises interfering with articulation. Still, by perseverance and with the aid of an occasional musically trained subject, I now, after more than ten years of study of the subject, whenever opportunity offered, and with the aid of a complete set of Rudolph Koenig's test tuning-forks and rods, feel justified to draw the following conclusions as being reasonably correct:

In the first place, I found that the ordinary tinnitus aurium due to middle-ear disease never transgressed the limits of pitch from "d-1," 297 vibrations as the lowest point, to the "f-2," 704 vibrations as the highest, as near as it was possible for me to determine, and that these subjective noises, although variable in quality or timber of the sound, had no appreciable effect upon vocalization or articulation; but that they would invariably and very materially affect the perception of sounds which had the same, or nearly the same, number of vibrations per second.

The subjective noises of so-called cinchonism as produced by the systemic toxic effects of various drugs, such as quinine, salicylate of sodium, alcohol, ether, and many others, I found to be invariably of a very high pitch, varying from as low as the "g-3" (1,584 vibrations) to as high as the "1-4" (3,960 vibrations) and often even higher. And in the few cases of musically educated persons whom I have had the opportunity to examine and who were familiar with aural analysis of sound, inquiry elicited the fact that the noise was composite in character, being made up of a variable number of individual sounds. These sometimes were harmoniously blended, thus forming a chord, the fundamental tone of which, however, was always constant in pitch, but varied in its pitch with the drug producing the cinchonismal noise, and was usually lowest if quinine was the cause, and highest when salicylate of sodium produced the subjective aural sensations—a fact which I have had frequent occasions to verify in my own person.

The third fact which I observed in this connection, and which should, by rights, be the first, because it was the one which led me to pay any attention to the subject at all, was that any composite noise of high pitch, such as is produced by the hissing of escaping steam or the noise of rapidly revolving grindstones, etc., not only interfered with the pronunciation of those consonants, which, according to the investigations of Helmholtz, Wolf, Seiler, and others, have for their characteristic (independent of vocal or vowel sound, by which they are usually accompanied in articulate speech) a combination of sounds of very high pitch, such as the "th," "s," "sh," "z," and the like consonant sounds of articulate speech, but also caused them to be the most easily obliterated and consequently most difficult to be appreciated and recognized by the ear. This fact which, if attention is called to it, is quite familiar to steam engineers, grinders, and others working among machinery can easily be explained by the well-known acoustic law of interference with each other of sound waves of the same or nearly the same length; and that the higher the pitch of two *non-harmonious* sounds, the greater the difference can be in the number of vibrations allowing interference. It is not necessary for a high-pitched noise, such as the hissing of steam, to be in unison with the noise of a consonant, the characteristic pitch or position in the musical scale of which is near that of the external noise, for the latter to react upon the former and to make its perception by the ear and production by the organs of articulation difficult, if not impossible.

But acoustic or physical laws fail us completely when a subjective, in reality physically non-existing, noise, such as that of cinchonism, materially interferes, as it undoubtedly does, with the *pronunciation* of those consonants of high-pitched composite characteristic sounds, and even alters the quality and timber of the high-pitched vowel sounds.

I offer this brief summary of facts as I have observed them, and refrain from any explanation or hypothesis of the to me inexplicable but undoubtedly existing influence of a purely subjective, and therefore non-externally, produced sensation upon a purely physical phenomenon, such as vocalization and articulation. But I hope that other and perhaps younger investigators may find them of use, and be able to turn them to practical account.

*Read at the annual meeting of the American Laryngological Association at New Haven, June, 1901.

French Snail Gardens.—As is well known, remarks the London *Morning Post*, certain species of snails form a favorite dish with French gourmets, and the cultivation of these land molluscs is conducted on a large scale in the outlying suburbs of Paris, particularly in the Department of Aube, where there are large snail gardens, with plantations of thyme, mint, parsley, and chervil for the animals to feed on. When a Frenchman takes snails wild, he, if prudent, leaves them a few days to digest their last meal, for there is a current belief that they may be dangerous if they have recently fed on poisonous plants.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, October 26, 1901.

MORTALITY RATE IN THE UNITED STATES.

THE statistics recently published by the census Bureau of this country with regard to the death-rates are of exceptional interest, and are of a nature to give rise to hopeful views regarding the checking of the spread of disease, and perhaps even the extinction of some maladies.

The mortality rates given in the bulletin are those for 1890 and 1900, and the comparison between the death list of these periods shows conclusively that the efforts made by hygienists to lengthen the lives of American citizens have been attended with complete success.

The statement is made that the proportion of deaths to population has decreased within the dates mentioned by nearly 10 per cent., and that the average age at death of an American is now 38.2 years, as compared with 31.1 in 1890. This, of course, is a magnificent showing, and the only drawback to the picture is that the bettered conditions of living apply only to the larger cities. The country districts exhibit according to the bulletin no such relative improvement.

The most striking feature of the report is the great reduction in the death rate from tuberculosis, which has fallen from 245.4 per 10,000 persons in 1890 to 190.5 per 10,000 in 1900, a gratifying proof of the efficacy of modern sanitation, and of the means now employed in fighting the disease. Diphtheria, cholera infantum, bronchitis, diarrhœa, and typhoid fever, also, for the same reasons, claim far fewer victims at the present time than in 1890, the decrease in mortality from these causes having been substantial and progressively steady.

On the other hand, pneumonia, as a factor in the death rate, occupies a more prominent position, there having been 191.9 per 10,000 deaths in 1900, and 186.9 per 10,000 in 1890. The cause of this increase in the occurrence of pneumonia has been on many occasions given in the RECORD, and in other medical journals as undoubtedly due to influenza. This insidious malady has made rapid progress since 1890. In that year, the deaths directly attributed to it were, the census bulletin states, 6.2 per 10,000, while in 1900 the number was 23.9 per 10,000. The fact must also be taken into consideration that influenza peculiarly predisposes its victims to other diseases, notably to pneumonia, by rendering the system susceptible in a high degree to the ingress of disease germs.

Pneumonia as a sequela to influenza is also a most fertile cause of death, the vitality of the patient when seized being at a low ebb, and recuperative powers well-nigh used up by the drain put upon them by the former affection.

Cancer, again, has been conspicuously on the increase during the past ten years, as have kidney complaints, heart affection, and apoplexy. The activity of scientific men in different parts of the world, who are engaged in the investigation of the origin and causes of cancer, give rise to the hope that some of its unknown features may soon be definitely solved, and that, as a consequence, its treatment may be conducted upon more intelligent preventive and curative principles.

The bulletin of the United States Census Bureau is a most satisfactory document, and the tale it tells is a feather in the cap of our city boards of health, and of our municipal reformers generally. There is yet, however, room for much improvement in the sanitary conditions of the large cities of America, particularly in the direction of wholesome dwellings for the poor.

THE GUILD OF THE DOCTORS.

IN all parts of the world, in which qualified physicians follow their calling, their souls are vexed within them, and their pockets suffer by reason of the strenuous competition encountered on all sides. As if it were not enough that the medical profession itself is full to overflowing, and that within its own ranks the struggle for position, and sometimes even for existence, must be continuous and unremitting —the additional burden of fighting the free lances of medicine and surgery is superimposed.

The most bitter drop in the medical man's cup of misery is the knowledge that the illegitimate practitioner, the faith curer, and charlatan of every description are permitted to contend on equal terms with the qualified man who has expended time, money, and brains in becoming competent to practise the healing art.

A case has come to light recently in Great Britain, peculiarly indicative of the anomalous situation in which a medical practitioner often finds himself in consequence of the laxness of the laws provided for his protection, and the strict adherence to the code of ethics, rightly prescribed by the governing medical bodies.

IT appears that the Duchess of Sutherland, a lady active in good works, conceived and carried into execution a scheme for the physical amelioration of crippled children in the Potteries district of Staffordshire. In that hive of human industry, owing to the conditions of life prevailing, an immense proportion of children are born into the world afflicted with a variety of diseases, many of which are curable. The duchess formed a league for the benefit of these unfortunates, and enlisted in her service the freely given aid of the doctors of the locality. Later on, however, she also called to her assistance a bone-setter well known in New York.

The *British Medical Journal* then urged the qualified practitioners to withdraw in a body as a protest against the introduction of the new incumbent. This perfectly regular and correct action on the part of the organ of the British Medical Association has aroused the ire, and inspired the sarcasm, of writers in many of the British lay journals, and in particular of a philosophic contributor to the *London Referee*, a journalist be it said whose writings are usu-

ally characterized by an impartial fairness and a sound common sense. The gentleman in question takes the ground that the point of the whole matter is that the bone-setter is not a member of a guild, and that in consequence the medical profession is prejudiced against him, without stopping to investigate his alleged skill in surgery.

There can be no doubt that the charge levelled against the profession, the British Medical Association, of being a guild, is correct, if by the term guild is meant a banding together of medical men for the protection of their own interests, and for the safeguarding of the general public against the wiles of incompetent persons.

The fact that the new man does not fall within this category does not weaken the position taken by the *British Medical Journal* in the least, but rather strengthens it, for if the distinguished bone-setter—who is, we believe, a Fellow of the Royal Veterinary College—possesses the knowledge of surgery and skill claimed for him, why, then, does he not qualify as a regular practitioner? The bone-setter has, according to authentic testimony, demonstrated a rare ability in the treatment of fractures and dislocations; he is not a fraud in this respect, and is thus so much the more dangerous; for numbers of impudent quacks, spurred on by his success and by the countenance given him by prominent and educated persons, have and will enter the same field, and, if not checked, will do an infinite amount of harm.

The truth is, probably, that he finds it much more profitable to keep outside the medical profession than to roam the world armed with a license.

An inherent weakness in human nature should also be taken into consideration, the tendency of a large number of persons, and especially of women, to believe rather in anything new, than in the established order of things.

So far, from the introduction of some of the principles of trade unionism into the medical profession being regarded as a reproach, it should be esteemed a necessary and sensible step, taken to preserve the interests of the medical man, and of the general public.

A far greater degree of cohesion than now prevails among the fraternity of medicine might exist with advantage to all concerned.

MASSAGE IN THE TREATMENT OF FRACTURES.

In *The Practitioner* for August, 1901, there is a contribution by Bennett of London on the value of massage in the treatment of fractures, and a number of important points of the subject are discussed. It is undoubtedly the case that many of the routine methods of treating simple fractures with various immobilizing splints, while fixation is secured, leave much to be desired in some other respects. The long-continued immobility produces stiffness of joints and tendons, causes œdema, and permits the muscles to atrophy, and any method which avoids these things, and at the same time does not allow any undue movements of the fragments, should receive attention. The great value of massage in the treatment of sprains has long been recognized, but the similarity of the conditions in fractures and sprains has not often been noted, though it undoubtedly exists. A sprain may be followed by extravasation, œdema, and involvement of tendons in the exudate in exactly the same way as in the case of fracture, and the treatment of these conditions in each case should be the same.

It is not entirely correct to think that absolute immobility of fragments is necessary after reduction has been accomplished, for under certain conditions of delayed union a little movement of the broken ends of the bone does more good than harm by stimulating the formation of callus. Indeed, it has long been a recognized way of hastening union in such cases of retarded or incomplete repair, viz., to move the partially united fragments vigorously on one another at certain stages in the treatment.

With means employed to prevent actual displacement of the fragments, we have, therefore, in a simple fracture the same conditions to contend with as in a severe sprain, and we may expect to get the same beneficial results from massage and passive movements as we are accustomed to obtain in the latter condition. The massage is rarely painful after it is employed the first time, and it may be made gradually more vigorous. The removal of the extravasated blood is thus completed much more quickly than is possible in any fixation method, and œdema is kept down practically completely. In the neighborhood of a joint, where extravasation and œdema are apt to be extensive, and where the tendon sheaths are liable to be filled with blood when the adjacent bones are fractured, the early removal of the extravasation has an important bearing on the future function of the joint and the tendons, and is a determining factor in the time required for the full restoration of function. Properly regulated massage is the only certain means of accomplishing this removal, and, combined with judicious passive movements, is coming more and more to be a recognized adjunct to the treatment of simple fractures. A shortening of the time of treatment is a matter of importance, since most of the persons who sustain fractures are those to whom sound bodies are a necessity in earning a living; and the picture of a man with the tendons of the wrist almost immobile and a somewhat œdematous hand, after the common fracture of the radius, undergoing manipulations sometimes for weeks, is only too well known to surgeons. If such tendons are not allowed to become adherent, and if the extravasation is provided for by massage, a much earlier return to work is possible.

In certain fractures, such as the patella, the olecranon, and the neck of the femur in old people, in which osseous union is not the rule, the early employment of passive movements and massage is of special value, and results are often specially prompt and satisfactory. In the case of the patella or olecranon, even after operative treatment, the early use of massage is valuable, and passive movements may be made with benefit at a much earlier date than is generally supposed, if made at right angles to the line of fracture, and of a very moderate extent at first.

It has been urged that massage in the presence of an extensive extravasation of blood will increase the danger of embolism, and is therefore of questionable utility. Under ordinary circumstances, thrombosis and embolism need not, however, be considered as any more likely to occur with massage than without

it, and it is only under special conditions that it must be used cautiously or not at all. When large vessels, especially veins, are in the neighborhood, and when the amount of contusion is extensive, it is conceivable that massage might dislodge a portion of a clot, and thus cause serious trouble, though under these circumstances accident seems to be a remote possibility, and more of a theoretical danger than anything else. Even when the extravasation is very extensive, the massage seems only to hasten its removal. Of course, if large veins are known to be in the region of the fracture, and to have been subjected to severe bruising force, no one would subject them to vigorous massage, though gentle massage and passive movements in the neighborhood outside the contused area would be valuable in restoring normal conditions of local circulation. The beneficial effect of massage in preventing muscular atrophy is well known and needs no comment, except to say that the after-treatment is much shortened when the muscles are kept in good condition, and that, in almost all cases of simple fracture, massage is therefore a desirable adjunct to the treatment. A considerable amount of dexterity, only acquired by practice, is necessary to get the full benefits of the plan of treatment which we are considering; but when systematically carried out the results will be very gratifying, and the number of fractures in which absolute and long-continued immobility is considered necessary will be very greatly diminished. Almost all simple, uncomplicated fractures of the long bones can be treated by this method, the chief care being that whatever in the nature of apparatus is employed should maintain reduction, and permit access to the site of the injury, so that the treatment may be carried out. The method is deservedly attracting much attention both here and in Europe, and so far has proved very satisfactory.

TREATMENT OF ACUTE PNEUMONIA BY OXYGEN.

Oxygen in the treatment of pneumonia is generally regarded nowadays with lessening favor, and much skepticism is evinced by a large number of medical men as to its beneficial remedial qualities. To such a large extent has this antipathy developed that the inhalation of the gas in cases of pneumonia would seem to be falling altogether into disrepute. It is, therefore, somewhat refreshing to meet with a practitioner who has a good word to say for gas, and who can point to a practical illustration of its merits as an enemy to the toxins of pneumonia.

According to Dr. Andrew H. Smith, pneumonia is not a direct inflammation of the lung, for the reason that in his opinion it does not affect the nutrition of the organ, but is a process of germ culture in which the pneumococcus grows in a medium supplied by the functional capillaries of the lungs. The cocci do not enter the lung substance, but are enclosed in the air vesicles, in which they flourish and produce their toxins, thus causing by absorption the fever and other characteristic symptoms of the malady.

The pneumococci of Fränkel do not thrive in pure oxygen, and this fact suggested to the mind of an ingenious physician that the inhalation of the gas might prevent the spread of the disease to healthy parts, and might probably prove inimical to those cocci which had already gained a footing in the lungs.

Dr. G. E. Richmond of the Imperial Yeomanry Hospital, Pretoria, South Africa, relates in the *Lancet*, September 28, his experience in the use of oxygen administered to a patient under his charge suffering from double pneumonia.

The man in question was young, fairly robust, and his temperature never rose above 104.6. The pneumonia was double. The disease progressed *pari passu* on both sides, until the upper lobes alone were left intact, and the patient fell into a typhoidal state, with respirations of 80 per minute and a pulse varying from 120 to 136. Dr. Richmond is of the opinion that if this condition had lasted a day or two longer, the patient must have died. From the time, however, the oxygen was given, the temperature began to fall, while before it had been rising. The patient made an excellent recovery.

Dr. Richmond remarks that whether this was due to the patient's constitution or the benign influence of oxygen is difficult to decide, but that he personally is disposed to attribute the favorable result to the action of oxygen in preventing the spread of infection to the upper lobes. The object in the treatment of pneumonia is to arrest or inhibit the growth of the pneumococcus, and when the extreme sensitiveness of the germ is considered, there would seem to be no reason why, if oxygen be antagonistic to the cocci, it should not check their spread.

The case against oxygen as a remedy in pneumonia is that in a large number of trials its beneficial effects have not been very obvious. On the other hand, delay in its use may have, in many instances, invalidated its action for good. Dr. Richmond only advises the use of oxygen in the early stages of pneumonia. Given then in conjunction with other remedies, oxygen may yet be found to play a useful part in the fight against the poison of the disease.

The Use of Insects as Food.—M. Dagin, a French entomologist, has recently written an article in which he recommends certain insects as an article of diet. He speaks with authority, having not only read through the whole literature of insect-eating, but having himself tasted several hundreds of species raw, boiled, fried, broiled, roasted, and hashed. He has even eaten spiders, but does not recommend them. Cockroaches, however, he says, form a most delicious soup. Pounded in a mortar, put through a sieve, and poured into water or beef stock, Dagin says they make a purée preferable to bisque. Wilfred de Fonvielle, the French scientist, prefers cockroaches in the larval state. The perfect insect may be shelled and eaten like a shrimp. Then, caterpillars are a light food and easy of digestion; not only African and American natives like them, but they are also appreciated by Frenchmen. M. de Lalande, the astronomer, dined every Sunday with the zoologist Quatremere d'Isjonvalle, and Mme. d'Isjonvalle used to collect caterpillars and serve them to the guest. The locust is much eaten by the Bedouins, and may be enjoyed fried, dried in the sun, ground into flour, boiled in milk, or fried and served with rice. The Jesuit father Cambon thinks that locust flour might become popular in Europe as a condiment. The precise opinions which are expressed by travelers as to locusts differ considerably. Amicis said that they taste like shrimps; Niebuhr, like sardines, and Livingstone, like caviare—another illustration of the differences of palatal appreciation.—*Medical Times and Hospital Gazette.*

News of the Week.

Celebration of Virchow's Eightieth Birthday in St. Louis.—One hundred and ten of the representative physicians and surgeons of St. Louis celebrated the eightieth birthday of Professor Virchow on the evening of October 12, by a banquet and speech-making. Dr. Robert Luedeking served as chairman and toast-master. The following addresses were delivered: "Rudolph Virchow," by Dr. Hugo Summa; "Virchow, the Pathologist," by Dr. Willard Bartlett; "What Hygiene Owes to Virchow," by Dr. A. N. Ravold; "Virchow's Work in Anthropology," by Dr. Robert Terry; "Virchow as a Public Man," by Mr. Chas. Nagel; "Medicine as a Cosmopolitan Science," by Mr. Perry Post Taylor. Drs. Schwarz, Spiegelhalter, Summa, Bernays, Luedeking, Barck, Bartlett, and Close acted as a committee of arrangements.

The New York Obstetrical Society.—At the annual meeting of the New York Obstetrical Society, held October 8, 1901, the following officers were elected for the ensuing year: *President*, Dr. Malcolm McLean; *First Vice-President*, Dr. J. Riddle Goffe; *Second Vice-President*, Dr. LeRoy Brown; *Recording Secretary*, Dr. George L. Brohead; *Assistant Recording Secretary*, Dr. George G. Ward, Jr.; *Corresponding Secretary*, Dr. E. E. Tuff; *Treasurer*, Dr. J. Lee Morrell; *Pathologist*, Dr. W. S. Stone.

Naval Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the Medical Corps of the Navy, week ending October 19, 1901: October 11—Assistant Surgeon F. M. Furlong, ordered to the Naval Hospital, New York, for treatment. October 14—Pharmacist J. M. Hurd, detached from the Boston Navy Yard and ordered to the *Wabash*. October 16—Surgeon S. H. Griffith, order to report for duty as a member of medical examining boards modified, ordered to report as a member of the medical examining board only, and not as a member of board for examination of medical officers. Dr. U. R. Webb, commissioned Assistant Surgeon from October 11, 1901.

The Association of Military Surgeons.—The following Committee of Arrangements has been named for the meeting of the Association of Military Surgeons of the United States, to be held in Washington, D. C., June 5-7 next: *Chairman*, Major George Henderson, Surgeon-General, N. G. D. C., 817 T Street, N. W.; *Members*, Major Louis A. La Garde, U. S. A., Major W. C. Borden, U. S. A.; Major F. P. Reynolds, U. S. V.; Captain E. L. Munson, U. S. A.; Surgeon S. E. Dickson, U. S. N.; Assistant Surgeon L. L. Williams, U. S. Marine-Hospital Service; Dr. George M. Kober, Dr. J. Ford Thompson, and Dr. Wallace Neff.

Examination for Assistant Surgeon of the Freedman's Hospital.—The U. S. Civil Service Commission announces that the examination fixed for October 29-30, 1901, to be held in any city in the United States where postal free delivery has been established, for the position of assistant surgeon at the Freedmen's Hospital, is postponed to November 12-13.

The San Angelo (Texas) District Medical Society.—A meeting was held in San Angelo, Texas, on the evening of September 23, at the call of Dr. Robert L. Greene, to organize a medical society. The name of San Angelo District Medical Society was selected, and Dr. S. L. S. Smith, the oldest physician, was elected President; Dr. Boyd Cornick, *First Vice President*; F. F. Tucker, *Second Vice-President*; Dr. Robert L. Greene, *Secretary*, and Dr. Bascom Lynn, *Treasurer*.

A New Cure for Cancer and Tuberculosis. Dr. W. Bezly Thorne writes to the *Lancet* that he has recently been a disinterested and, he believes, unpartial observer of a number of cases of cancer and of pulmonary tuberculosis which are at the present time undergoing treatment without the aid of drugs at the hand of a physician and an expert in electrical science, whose desire it is that their names should for the moment not be divulged. The cases of tuberculosis are all in the stage of cavitation; those of cancer have, with one exception, been pronounced by authorities well known to the medical world to be hopeless. All those which have been more than a week under treatment, he says, are both as to local conditions and general health in a state which, to all appearance, is one of imminent cure. Very shortly, he adds, there will be given to the medical profession a full statement of these cases and a detailed account of the means and methods which are being brought to bear on their treatment.

Virtuous Indignation of Sir Dyce Duckworth.—In a recent issue of the London *Spectator* appeared a letter signed by a physician of that town, named Sir Dyce Duckworth, in which the medical attendants of President McKinley were soundly berated for the bulletins which they issued concerning the condition of their patient. The illustrious critic expressed the opinion that these bulletins were furnished with but slender regard to the decency and respect due to the privacy of the patient, and that many related to matters of treatment which were obviously unfit to be read, much less to be discussed, by the general public; and he also informed the British public that the publication of such bulletins was a new departure and a bad example afforded by America. Of course, he is wrong as to this statement, for the publication of bulletins when any illustrious person is seriously ill is a very old and laudable custom. There was, furthermore, nothing in the official bulletins to offend against the decency and respect due the patient. Sir Dyce seems to have been at loss for something to write about, and we fear he has laid himself open to another reproof from the *Lancet*, which some years ago called him to account for an item, prominently published in a society paper, announcing that "Sir Dyce Duckworth the well-known physician, has gone to America. He intends to be back in this country September 16." The *Lancet* seemed to think that the visitor to our shores was hardly of sufficient importance as a public character to have his movements so definitely recorded simply as a matter of news.

Trouble in the New Rochelle Hospital.—It is reported that the attending physicians and surgeons of the New Rochelle (N. Y.) Hospital have resigned because of the action of the Governor in limiting the term of service of the staff to one year, although not forbidding reappointment. The medical staff maintains that, although the Governors had the legal power, they had not the moral right to do it, because of an agreement between the physicians and the hospital association that the staff should have a permanent tenure, and no member should be removed without cause, and only on charges, after trial before the medical board.

A Family of Suicides.—A man named Edgar Jay Briggs, who hanged himself on his farm, near Danbury, Conn., a few days ago, was almost the last surviving member of a family which has practically been wiped out of existence by suicide. The history of self-destruction in this family extends over a period of more than fifty years, and in that time, so it is stated, at least twenty-one of the descendants and collaterals of the original Briggs suicide have taken their own lives. Among these were the great-grandfather, grandfather, father, brother, and two sisters of the one just dead. Many of the suicides were effected in an unusual way.

One man drowned himself by holding his face in a shallow brook, another attached a weight to a collar about his neck and then waded into a pond. Others shot or hanged themselves in a way evidencing fixed determination to end their lives. All of the suicides were not blood relations, some being women who had married into the family. If the newspaper accounts, from which we have quoted, are correct, this is certainly a remarkable instance of contagion of the suicidal impulse which deserves accurate study and record.

Malaria as an Antidote to Cancer.—Professor Loeffler has suggested the inoculation of a cancerous patient with malaria as a means of cure of the malignant growth. He thinks he has discovered an antagonism between the two diseases, asserting that cancer is a rare disease in tropical countries where malaria is rife.

Partial Failure of Antivenene.—Dr. Calmette of the Pasteur Institute at Lille was recently, as we noted at the time, bitten by a cobra during the course of some experiments he was making. He immediately injected subcutaneously a dose of antivenene which had been prepared by himself, and his life was preserved. He was not saved, however, from all the consequences of the injury, for it was found necessary three weeks later to amputate the bitten finger, on account of gangrene which set in soon after the accident.

The Plague.—It is officially announced that Naples is now entirely free from plague, no new cases having developed after the disease was discovered, and the sick were isolated. At Rio de Janeiro there were on Sunday last fifty-two cases of plague, two or three new cases being reported daily. In Foo-Chow, China, the disease is raging, if a report in the London Church Missionary Society is correct, according to which the number of new cases average 1,500 daily.

The Contagion of Leprosy.—The newspapers publish a dispatch from Copenhagen stating that City Physician Feilberg of that place, who recently visited the West Indies, is suffering from a marked case of anæsthetic leprosy, which he is believed to have contracted from a patient whom he attended while in the West Indies.

Dr. Sternberg on Yellow Fever.—In his annual report to the Secretary of War, Surgeon-General Sternberg, himself an acknowledged authority on yellow fever, adds the weight of his official approval to the mosquito theory. He says: "The results obtained were especially valuable, showing that the bacillus icteroides (Sanarelli) bears no causative relation to yellow fever, and that the mosquito serves as an intermediate host for the parasite of this disease. Further experiments of a most interesting character demonstrated that yellow fever is transmitted to non-immunes by the bite of a mosquito that has previously fed on the blood of those sick with this disease; that yellow fever can also be produced by the subcutaneous injection of blood taken from the general circulation during the first and second days of the disease; that an attack of yellow fever produced by the bite of the mosquito confers immunity against the subsequent injection of infected blood; that yellow fever is not conveyed by clothing, bedding, or merchandise soiled by contact with those sick with the disease; that a house may be said to be infected with yellow fever only when there are present in it mosquitos capable of conveying the parasite of the disease, and that the spread of yellow fever can be most effectually controlled by measures directed to the destruction of mosquitos and the protection of the sick against the bites of these insects." He adds that the results of these investigations are of far-reaching importance, as the surgeons are now in possession of knowledge which enables them to stamp out yellow fever.

Faith Curists in Trouble.—The Butler County (Ohio) grand jury recently returned indictments for manslaughter against a man and his wife, faith curists, whose eight-year-old child, Esther, was burned by a gasolene explosion last July. The parents declined to call a doctor, but surrounded the child's bedside with members of their sect, offering prayers for her recovery. The coroner in his verdict said that medical attention would have saved the girl's life. A second indictment for criminal neglect was returned against the father. In Chelsea, Mass., a prominent Christian Scientist has died of typhoid fever. For three weeks he grew worse under treatment of one of the "readers" of his sect, and then they called in a physician. He did what he could for the man for a few days until death occurred. In his certificate of death the physician, Dr. Leeds, stated that the primary cause of death was typhoid fever, and the contributing cause was Christian Science. He said that while it was, of course, not certain that the victim would have recovered if a doctor had been called in to the case early, it was certain that the lateness in calling a doctor greatly reduced the patient's chances for life. The man had a strong constitution, and his chances for recovery should have been excellent.

Leprosy in Hawaii.—According to a recent report of the Marine Hospital authorities in Hawaii there are now 909 lepers and 164 healthy persons in the leper settlement of Molokai. The cost of the settlement, including the housing, feeding, and clothing of these persons, is about $80,000 per annum. The three oldest patients at the settlement arrived in 1874, 1875, and 1879, respectively. The number of commitments to the settlements each year during the last decade, ranging from 132 in 1891 to 85 in 1900, show a gradual decrease, despite the fact that the hunt for lepers throughout the islands has never before been so vigorous.

A Beginning of Fair Play for Women in Germany.—The two German women, Dr. Irma Klausner and Elsa von der Leyen, who were the first ladies to take their degree and pass the German medical state examination, have now settled at Berlin, where they intend to practise as physicians. Now, that this is allowed in Germany, it is believed that a great number of ladies will study for their medical degree in Berlin.

Mosquitos Attracted by Sound.—Major Ronald Ross writes to the *British Medical Journal* that he has recently received a communication from Mr. Brennan of the Public Works Department, Jamaica, containing the following observation: "You will pardon me for drawing your attention to the fact, if you have not already noticed it, that the mosquitos (I do not know if every variety) will respond to such sounds as a continuous whoop or hum. I have tried the experience lately, and find swarms gather round my head when I make a continuous whoop. There may be, however, some particular note or pitch that would be more attractive to them." This would afford an interesting subject for investigation, the journal quoted remarks, on the lines of Dr. Nuttall's recent research on the colors attractive to mosquitos.

The Alvarenga Prize.—The College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Senor Alvarenga, and amounting to about $180, will be made on July 14, 1902, provided that an essay deemed by the Committee of Award to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but cannot have been

published and must be received by the Secretary of the College on or before May 1, 1902. Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author. It is a condition of competition that the successful essay or a copy of it shall remain in possession of the college; other essays will be returned upon application within three months after the award. The Alvarenga Prize for 1901 has been awarded to Dr. George W. Crile of Cleveland, Ohio for his essay entitled: "An Experimental and Clinical Research Into Certain Problems Relating to Surgical Operations."

Some Alleged Old Folks.—A recent cable dispatch from Athens records the death at Khuti, Albania, of Ismail Hudjo, said to have been the oldest man in the world. It is said that he was 160 years old. His faculties were unimpaired, and he had all his teeth when he died. He leaves 200 descendants. On the same day a telegram from St. Joseph, Mo., announced that Mrs. Ann Taylor, one of the historical characters of that city and State, had died there aged 110 years. For more than a century she had been addicted to the use of tobacco and liquor.

The Need of a Gall-Bladder.—Dr. Joseph D. Bryant writes: "In the report of the meeting of the Medical Society of the State of New York (page 633), I am made to say regarding the need of a gall-bladder: 'Whereas, those whose diet consisted of proteids entirely, could scarcely live without it' (p. 633).

"On the contrary, I made the statement that in many instances its removal from dogs had not been followed by any appreciable change after a long time."

Obituary Notes.—Dr. Charles Henry Brown of this city died on October 15. He was born in New York on June 18, 1856, and was graduated from the New York University Medical School in the class of 1879. For many years prior to his death he was Managing Editor of the *Journal of Nervous and Mental Diseases*. He was a member of the Medical Society of the County of New York, of the Academy of Medicine, of the New York Neurological Society, and of the American Neurological Society.

Dr. Horace Bigelow of this city died in Roosevelt Hospital on October 15 of pneumonia. He was born in Fayetteville, N. Y., in 1873, and was graduated from the Medical Department of Columbia University in the class of 1896, subsequently serving on the house staff of Bellevue Hospital.

Dr. Hannah E. Longshore, one of the pioneer woman physicians in Philadelphia, died in that city on October 18 at the age of eighty-two years. She was graduated from the Woman's Medical College of Pennsylvania in the class of 1852, and was appointed demonstrator of anatomy immediately upon graduation. She practised medicine for about forty years, retiring about ten years ago.

Dr. Henry Raymond Rogers of Dunkirk, N. Y., died on October 19, at the age of eighty years. He was a graduate of the Jefferson Medical College in the class of 1851. He was a member of many years' standing of the American Medical Association.

Dr. Joseph Sanders of this city died at Oil City, Penn., on October 20, of typhoid fever. He was born in New York City on July 6, 1867, and in 1892 he was graduated from Bellevue Hospital Medical College. After a period of post-graduate study in various German universities he began the practice of medicine here in 1895. At the time of his death he was Assistant Chief of the Nose, Throat, and Ear Dispensary of Mount Sinai Hospital. Dr. Sanders was a member of the Academy of Medicine, County Medical Society, and the German Medical Society.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

OPENING OF THE SESSION—INTRODUCTORY LECTURES—GENERAL IAN HAMILTON ON THE R. A. M. C. REORGANIZATION—THE SMALLPOX EPIDEMIC—THE DROUGHT.

London, October 4, 1901.

The schools are now at work, the opening day having been duly celebrated, though in a fashion less impressive than formerly. Dinners and entertainments are more and more displacing the introductory lecture, but some of the schools still adhere to the time-honored custom, and the addresses certainly contrast favorably with the post-prandial speeches.

At Charing Cross Hospital, Professor Taylor of Birmingham gave the lecture, which he began by remarking that, though this marked to many their acceptance of the medical career, the choice they had made was of far less importance than the manner in which they would follow it. It may matter little, he said, to a man whether he is a soldier, sailor, doctor, clergyman, or lawyer, but it will matter very much afterward whether he acted as became a man called to the duties and responsibilities of his chosen life. He then referred to the requirements for successful service, such as a healthy, well-trained body, a well-educated mind, and a high moral purpose. The last of these he pronounced of the greatest value, and commented on the increasing perception of its importance as life advanced. Having referred to the qualities which go to form the ideal doctor and instanced love of truth, love of his fellows, and love of service, he asked, "And, after all, what if we know we are wanting?" Then, he said, it is necessary to insist on the gospel of true education, especially while so much nonsense is scattered broadcast about heredity. "There is no weakness you cannot grow out of if you set your heart upon it; no strength or goodness you may not aspire to, and in some measure attain."

At the Middlesex Hospital, Dr. T. H. Kellock dilated on the relations between hospitals and students during their pupilage and afterward. Hospitals provide the best instruction and all the new and costly things required by the progressive medicine and surgery of to-day. On the other hand, the student could help the hospital while acquiring knowledge, both by the faithful discharge of his duties as dresser or clerk and his careful behavior in the wards and other departments, and even outside the walls. After he left and was in practice, a visit to his old hospital would always be profitable and better than post-graduate courses. By working together, too, hospitals and general practitioners can educate the public to keep hospital abuse within moderate limits.

At St. Mary's Hospital, Dr. Wm. Hill spoke of quackery and superstition, tracing their connection with medicine from the earliest times, to show that theology has really nothing to do with the investigation or treatment of disease. At the outset of his lecture, he commented on the surprising fact that nearly 2,000 persons should annually enter on an expensive course of study to prepare for a profession already overcrowded. On this point, he took a more gloomy view of the prospects of the new students than some of the other lecturers, and than most of the persons I have heard speak about it.

At St. George's Hospital, Dr. P. W. Latham of Cambridge took for his subject "Medical Study," on which his experience at the University gives him considerable authority. He advised men not to devote more than a due share to preliminary studies—the two years which are compulsory are also enough. At Cambridge, 50 per cent. of the medical students he found did not take their M.B. Five years constitute the curriculum required by the Medical Council, but Cambridge graduates take usually seven or eight. Some, no doubt, yield to the allurements of pure science and abandon medicine, but there must be other causes in operation for such a result. Dr. Latham pointedly told his audience not to attempt to cram too much science in the time at their disposal, but to learn what was really required, and then, above all, to learn to apply what they really did know.

Dr. Risien Russell welcomed the students at University College, and in the course of the introductory discussed the influence of their chosen school on medical education. He held that the teaching there is unsurpassed by any in this country, and begged his hearers to cultivate the spirit of scientific inquiry exhibited by so many of their predecessors. As an incentive to seek the advance of medical science he suggested the reading of the horrors of surgery before the days of antiseptics, and contrast them with what they would see in the hospital. This might stimulate them to emulate men like Lister, who could very well

ignore the vituperations of a gang of agitators in face of the benefits his researches had conferred on his fellow creatures.

Dr. Russell also advised his hearers to become "good all-round men," though he emphasized the growing importance of bacteriology and chemistry. He called their attention to the prospects of their future, taking a rather optimistic view, in support of which he instanced the falling off of the number entering the profession since 1893, when it may be objected there was a state of overcrowding from which we have not recovered.

The reorganization of the army medical service would, he thought, induce an increase of candidates, and a similar reform of the naval department must follow. The attraction of men to these and other public services was calculated to leave more room for private practice. He thought, therefore, that those who would be ready to begin practice five or six years hence would find satisfactory prospects.

Complaining of the unsatisfactory status of the profession with the public, he attributed it to the way in which some of its members comported themselves, even some occupying high positions. He thought, too, that dispensing their own prescriptions hindered the due appreciation of the public, who were apt to confuse the doctor with the mere vendor of drugs. The abolition of the custom of supplying the medicines they prescribed would, Dr. Russell considered, teach patients to value the practitioner for his advice and give him more time to keep up with the advances of medical science.

Another aspect of this subject was treated by Dr. A. P. Luff, who delivered the address at the Pharmaceutical Society. He pointed out that the art of prescribing is declining through the fatal tendency of practitioners to accept indications from manufacturers. He held it to be a travesty on the art to order, say, No. 4 mixture (Smith & Jones). It was degrading to compel the scientific pharmacist to hand over such a proprietary article. It was degrading to a qualified practitioner to exploit such a puffed and probably over-vaunted article. Such prescribing he put on a par with the dosing sometimes carried out on a ship which carried no surgeon, but had a medicine chest, with numbered bottles and a guide book to indicate the numbers called for by certain symptoms. The captain who, when No. 9 ran out, mixed equal parts of Nos. 4 and 5 displayed a similar intelligence. Dr. Luff further dwelt on the danger of self-drugging by the public, which is fostered by the uncontrolled sale of powerful drugs in tablet form. Many of these, he said, do infinitely more harm than the quack medicines they partly replace; for tablets often contain dangerous doses, while many of the nostrums are to a great extent innocuous. The cocaine habit has been greatly fostered by the exploiting of tablets, and another pernicious craze, the uric-acid diathesis, was pandered to by unscrupulous advertisers. In consequence, it was no uncommon thing to see at a dinner party neurotic young men dropping lithia tablets into their champagne to counteract what they fancied to be its acidity, lacking, as they did, gastric vigor to deal with the wine, and moral vigor to abstain from it.

Among other openings I can only mention St. Thomas's, and that because Major-General Sir Ian Hamilton came, distributed the prizes, and made a most interesting speech. After a very pretty compliment to the profession as one "who had seen doctors in the field," he considered the new scheme for the reorganization of the R. A. M. C., which has just been promulgated. He took a very favorable view of it, and believed it retained what was good in the system, removed the bad, offered much advantage to the doctors, and would revivify a corps which in matters purely professional had fallen upon evil times. Let us hope the anticipation may be realized. "The scheme should be read between the lines," he said, and described it as a framework of which its possibilities in sympathetic hands were promising. This may be true—the first look at it appears so. But it is only a scheme on paper, and the hands to work it are by no means sure to be sympathetic. Yes, it promises well—on paper—but the "trail of the serpent (*i. e.* War Office) is over it all," and with every disposition to agree with Sir Ian, I cannot help seeing the slime. It will not, therefore, surprise me if its promise is broken. It is not easy to forget the many former promises which have been ignored, even the Royal Warrant has been set at naught.

Smallpox continues to spread, and the whole of London may be regarded as an infected area. From six to eight cases have been added to the admissions on most days, but on Saturday there were twenty and yesterday twelve. The number remaining now under treatment is 187. The return of thousands of hop-pickers constituted a serious danger, as the disease had been reported on some of the fields; one virulent case had come from this employment, and Dr. S. Murphy, the Medical Officer of the County Council, was consulted. As a result, a kind of picket of the railway was arranged, and about 700 passengers examined. Five or six cases were detected, and removed to the hospital. Other stringent measures have been adopted, trains are still being watched, and persons returning from infected districts are kept under observation. Posters setting forth the importance of revaccination have been affixed by some of the authorities, and free vaccination is offered. Assistant vaccinators have been temporarily appointed, and one of them says he has been vaccinating about 300 a day for the last week. The middle classes are undergoing revaccination by their own doctors, and it is a common thing to meet men with a tape tied on their arm to signify it is still tender. If the anti-vacs have any perception, they must see that the masses prefer the temporary inconvenience of a sore arm to the risk of a loathsome disease, and the judgment of the profession to the prejudices of cranks. In some districts, a house-to-house visitation has been made. At Aldershot, the soldiers are being revaccinated.

The drought in the North has been relieved by some rain, but not nearly enough so far to avert the danger. Many factories are closed for want of a supply, and households are still on short allowance. Telegrams yesterday announced some rains. There has been a very heavy fall here, and we may hope the northern towns are sharing the benefit.

OUR PARIS LETTER.

(From Our Special Correspondent.)

GONOCOCCIC ENDOCARDITIS—PHOTOTHERAPY IN THE TREATMENT OF LUPUS (LEREDDE)—A NEW THERMO-CAUTERY—ELECTRIC TREATMENT OF MUCO-MEMBRANOUS COLITIS.

PARIS, October 3, 1901

THE gonococcus as a cause of septic endocarditis has been looked upon with some suspicion, but recent examples cited, not only in America, but also in Germany, show that the heart may be affected seriously by this infection. Dr. Wassermann of Munich has described a case in a man twenty-seven years old. He had no hereditary antecedents, and had already had gonorrhœa three times. This last attack was treated by injections of permanganate of potassium. After six weeks' treatment, the attack seemed to be cured, but eight days later the urine became cloudy, micturition painful, and there were signs of partial retention. Catheterization was performed, and two liters of urine were removed. The patient was removed to the hospital, where the urine was found to contain albumin. The temperature was over 39° Celsius. Nothing was found on examining the heart and lungs. Local treatment was applied, but gave no result. Death took place on the fifth day. The autopsy revealed an abscess of the left part of the prostate, incipient nephritis, and cystitis, with ecchymoses of the mucous membrane. The heart showed a slight degree of hypertrophy of the left ventricle. On the aortic valvulæ were to be found, near the free edge, wart-like excrescences of a grayish-red color. Microscopical examination showed diplococci, which proved, on being cultivated, to be gonococci.

The treatment of lupus by such methods as electricity and phototherapy has been investigated of late by the French dermatologists, and they have recently published the results they have obtained by these therapeutical agents. Dr. Leredde, former chef de clinique at the St. Louis Hospital, has founded a private clinic somewhat after the German plan, and he has treated several cases of lupus by phototherapy. In an article he has just published in the *Presse Médicale*, he gives a few characteristic reactions produced by its use. The first and most important one is that it acts below the surface, sometimes being able to pass through the thickness of the cheek. Another is that the photogenetic reaction does not seem to destroy the tissues. The apparatus of Finsen can be left in place two hours, that of Lortet and Genoud forty-five minutes, without any noxious effect. Some redness and the appearance of phlyctenes are the only modifications to be noticed. This is far from being the case with Röntgen rays. Cicatrices are generally quite perfect, nor is there any subsequent pigmentation. There is not much pain produced by the use of phototherapy (the writer knows of one case where there was intense pain). Two different types of apparatus are being used at present, that of Finsen, which is undoubtedly already known in America, and the one invented by Professor Lortet and Dr. Genoud. In the latter, what has been aimed at is to place the patient as near as possible to the lamp. A much weaker arc is used, of only 10 to 20 amperes. A current of water is made to pass around the lamp, and the rays are centralized by lens. By means of this modified apparatus, it is not necessary to expose the patient to its effect more than a quarter of an hour. Moreover, the cost of such an apparatus is much less than that of

Finsen. The great objection made to Finsen's method was that it could only be used for wealthy patients, or where a great outlay could be made easily. This is no longer true with Dr. Lortet's apparatus.

Dr. Leredde established a comparison between phototherapy and the older methods, such as galvano-cauterization, scarification, or total excision. He stated it was more advantageous to use one or the other method, according to the form observed. Galvano-cauterization and scarification should be tried, but not too long, as the cicatricial tissue produced thereby hinders the action of phototherapy. In erythematous lupus, the electric current would seem to be more advantageous, according to Jacquot. Still, in some cases phototherapy proves to be the only true remedial agent. A practical distinction should be made, according to Brocq, between aberrant lupus and localized lupus, as the treatment is not the same in both cases. In the first case, such agents as black soap, pyrogallic or salicylic acid, mercurial plasters, or electricity are efficacious, whereas in the other they may fail to produce the required result. The treatment of nævi by phototherapy has not as yet produced important results. Dr. Leredde does not believe in treating epithelioma of the skin by phototherapy unless there are special indications. Such lesions should be seen to by surgeons.

Paquelin's cautery, which has been used so much of late years, has diminished in price during the last three years on account of the time-limit of its patent having expired.

It is, however, a cumbersome instrument, and another one has been invented, the aphysocautery, which can be handled much more readily. It resembles the ordinary cautery, but the handle is hollow and contains a small reservoir of ether, which serves to keep the cautery incandescent. This instrument would seem to be dangerous, but it is built so that it can resist a pressure of 30 atmospheres.

The therapeutics of muco-membranous colitis do not give satisfactory results in many cases. Dr. Doumer, a Belgian physician, has tried electricity in several cases and advocates it strongly. One patient was suffering from constipation accompanied by muco-membranous colitis and stenosis of the ascending colon. All sorts of treatments had been tried. He was subjected the first day to a 30-milliampere current during ten minutes. The following days the current was slowly increased to 70 and 80 milliamperes, and after ten days the constipation disappeared, as well as all the other symptoms. Five other patients reaped the same benefit from this treatment. The technique adopted by Dr. Doumer is as follows: Two large tampons of coal, 6 cm. in diameter, are covered with chamois skin, dipped in water and placed in the iliac fossæ. The current used is at first only of 30 milliampere strength. Later it may be increased to 120 or 150. This treatment should be kept up ten to twelve days.

The Annals of the Pasteur Institute, a journal published monthly, has recently given the proportion of deaths from hydrophobia after treatment at the Pasteur Institute. In 1886 the percentage was 0.94 per cent.; in 1887, 0.79; in 1888, 0.55. It has been going down steadily since then, and during the last three years out of 4,499 cases there have been only eleven deaths, or a proportion of 0.25 per cent. It is worth while noting that, according to the statistics of Tardieu, Thamhayn, and Bouley, when no treatment has been followed, the percentage of deaths is 46.6 per cent.

AWARDS OF INTEREST TO MEDICAL MEN MADE AT THE PAN-AMERICAN EXPOSITION.

(From Our Special Correspondent.)

BUFFALO, N. Y., Oct. 16.

THE list of awards to exhibitors at the Pan-American Exposition contains many items of interest to medical men, a number of whom have themselves received recognition as exhibitors, either directly or through the institution, organization, or association through which their exhibits were made. This is particularly the case with respect to the exhibits in the sections on public hygiene, hospitals, and sanitaria, and similar institutions. While services as collaborators are also to be officially recognized, this matter has been left for subsequent action by the Exposition authorities, to whom the recommendations of the juries of award on this matter have been referred. In making the awards, the juries took into consideration only the absolute merits of the articles judged, and had no regard for the commercial, scientific, or professional standing of the parties making the display. For this reason, a low award made upon an exhibit could not be construed as being, in any way, a reflection upon the standing of the institution making the display. As an instance, the poor showing made by a certain board of health, whose great practical efficiency was well known to the jury of award, resulted in the withholding of any special recognition of its exhibit by the Exposition authorities. This did not mean that the board of health in question was inefficient, but that the evidence of its workings, as submitted to the public at the Exposition, was of inferior character. A question that arose very early in the sittings of the juries concerned itself with the standard of comparison to be adopted. Were the exhibits in the same class to be compared with each other or were all to be compared with an ideal standard? The discussion of this question resulted in the rule by which an ideal standard was created; this ideal being based upon the highest state of an art under present conditions rather than upon the possible or anticipated developments of such an art in the future. Under this ruling it was possible for more than one exhibit in the same class to receive the highest award; but, on the other hand, no award was granted, merely because of lack of competition. Obviously, the granting of awards of the same grade to entirely dissimilar objects or exhibits implied no comparison between them. A subject for complaint on the part of some who had exhibited at the Paris Exposition was that exhibits which had received gold medals at Paris only obtained silver or bronze medals at Buffalo. At Paris, however, there were five grades of award, the highest being the "Grand Prix," while the Pan-American had but four grades of award, and recognized nothing higher than the gold medal. Exhibits were thus necessarily graded, with respect to awards, one grade lower at Buffalo than at Paris.

While the exhibits of the various departments of the United States Government were not entered in competition for award, the Exposition authorities gracefully acknowledged their obligations to these departments by appointing a special jury to examine their exhibits, report upon their importance and characteristics, and to submit recommendations upon which appropriate recognition might be made to such departments and those assisting in the collaboration of their exhibits. This special jury made the following remarks and recommendations with respect to the exhibits of the medical departments of the army, navy, and marine hospital service:

"The medical department of the army has established immediately south of the Government Building a model brigade field hospital. Seldom has the public been able to inspect such an exhibit. It is especially interesting since it represents the new equipment of the medical department in the field—scarcely an important article of which has not been adopted since the outbreak of the war with Spain, and has never been shown previously. A detail of enlisted hospital corps men give daily exhibition drills in first aid to the wounded, litter drills, demonstrations of various means of transporting the wounded, tent pitching, and hospital establishment. The drills are very popular, and in connection with them the hospital forms a most complete and creditable exhibit of the medical service of the army." In the grading of the exhibits made by the various bureaus of the War Department for recognition in respect to their importance, that of the medical department was placed first on the list.

With respect to the exhibit of the medical department of the navy, the jury says: "The bureau of medicine and surgery (exhibits) a complete sick-bay as constructed and equipped on a man-o'-war, and a model of the hospital ship *Solace*." The display was graded second in the list of the exhibits made by the various bureaus of the Navy Department.

Concerning the exhibit of the marine hospital service, the jury says: "(There is a) model of a fully equipped marine hospital ward, models of different quarantine stations established by the Government, and other exhibits illustrating the great care the marine hospital service is taking to prevent the introduction and spread of contagious diseases and epidemics." This exhibit was graded by the jury fourth in relative importance of the exhibits made by various bureaus of the Treasury Department.

In the general subjects of hygiene, sanitation, and public health, the following exhibits from the United States were found worthy of award, the awards being listed alphabetically according to the names of the respective exhibitors:

Gold Medals.

1. Abbott, Dr. Samuel G., Boston.—Collection of material relative to public hygiene.
2. Bath Department, City of Boston.—Public hygiene.
3. Chicago Department of Health.—Sanitation.
4. Health Officer's Department, Quarantine, Staten Island, N. Y.—Sanitation.

5. Massachusetts State Board of Health, Boston.—Sanitation.
6. Tenement House Committee of the Charity Organization Society, New York City.—Models, photographs, and plans.

Silver Medals.

1. Buffalo Health Department, Buffalo, N. Y.—Sanitation.
2. Maine State Board of Health, Augusta.—Sanitation.
3. Michigan State Board of Health, Lansing.—Sanitation.
4. Prudential Insurance Company, Newark, N. J.—Vital statistics.
5. Street Cleaning Department, New York City.—Sanitation.

Bronze Medals.

1. Buffalo Society for Prevention of Tuberculosis, Buffalo.—Sanitation and public hygiene.
2. Bath House Committee, Brookline, Mass.—Public hygiene.
3. Boston Health Department, Boston.—Sanitation.
4. Connecticut State Board of Health, New Haven.—Sanitation.
5. Philadelphia Board of Health, Philadelphia—Sanitation.
6. Pittsburg Board of Health, Pittsburg.—Sanitation.

Honorable Mention.

1. Maryland State Board of Health, Baltimore.—Sanitation.
2. New Hampshire State Board of Health, Concord.—Sanitation.
3. Providence Board of Health, Providence, R. I.—Sanitation.
4. Rhode Island State Board of Health, Providence, R. I.—Sanitation.
5. Vermont State Board of Health, Richford.—Sanitation.

Beside the exhibits which received the above awards, there were about sixty others which were not regarded by the jury of awards as being possessed of sufficient merit to entitle them to any special recognition. The exhibits relating to public health consisted chiefly of charts, statistics, photographs, reports, and blank forms for use by health officers and others, together with a few models. The exhibits from Massachusetts and the city of Boston and vicinity were of a particularly high order, and reflected much credit on those in charge. To Dr. Abbott, for his excellent work in bringing together such a valuable collection of material relating to public hygiene, the jury awarded a gold medal. It is understood that this collection, which was got together by him for the Paris Exposition, is to be returned to the collector at the end of the present Exposition. It would be highly desirable if it might be turned over by him to the Surgeon-General's Library in Washington or the Naval Museum of Hygiene, where it would be more generally accessible to those interested than in any other location.

On sanitary plumbing, fixtures, and appliances the following awards were made:

Gold Medals.

1. American Encaustic Tiling Co., New York City.—Sanitary flooring.
2. Mott Iron Works, New York City.—Model bathroom and fixtures.
3. Perfect Sanitary Flooring Manufacturing Co., New York City.—Sanitary flooring.
4. Standard Sanitary Manufacturing Co., Pittsburg.—Sanitary fixtures and plumbing.

Silver Medals.

1. Hyde Furniture Co., Rochester, N. Y.—Sanitary public drinking-fountain.
2. Trenton Potteries Co., Trenton, N. J.—Sanitary earthenware.

The samples of sanitary flooring receiving high awards consisted of cemented tiling and of small marble chips laid in cement and rubbed down to a smooth finish. Both were admirable from a sanitary standpoint, but the remarkable decorative possibilities of the American Encaustic Tiling Company's product must be seen to be thoroughly appreciated. The model bathrooms and displays of sanitary fixtures made by the Mott Iron Works and the Standard Sanitary Manufacturing Company were both not only attractive to the eye, but admirable from a sanitary standpoint. The Hyde Drinking-Fountain furnishes uncontaminated drinking water for public places, and marks a distinct sanitary advance in this respect. The apparatus, however, is not without certain minor defects which require remedy. In general, the exhibit of sanitary appliances was not large, but the articles shown were of generally excellent character.

The following awards were made upon exhibits having to do with hospitals, sanitaria, and hospitals for the insane:

Gold Medals.

1. Johns Hopkins Hospital, Baltimore.—Plans, photographs, reports, and publications.
2. McLean Hospital for Insane, Waverly, Mass.—Photographs, etc.
3. McGarr, Thos. E., Albany, N. Y.—Services in collection of material relating to hospitals for the insane.
4. Presbyterian Hospital, New York City.—Model, plans, and reports.

Silver Medals.

1. Boston City Hospital, Boston.—Photographs, plans and reports.
2. Municipal Hospital for Insane, Pierce Farm, Boston, Mass.—Photographs, etc.

Bronze Medals.

1. St. Luke's Hospital, New York City.—Photographs, etc.
2. St. Mary's Hospital for Children, New York City.—Model of hospital ward.
3. Worcester Hospital for Insane, Worcester, Mass.—Photographs, etc.

Honorable Mention.

1. Buffalo General Hospital, Buffalo, N. Y.—Photographs, reports, etc.
2. Charity Hospital, New Orleans, La.—Photographs, reports, etc.
3. Hospital of St. John's Guild, New York City.—Photographs, etc.
4. Roosevelt Hospital, New York City.—Photographs, etc.
5. Sloane Maternity Hospital, New York City.—Photographs, etc.
6. St. Lawrence Hospital for Insane, Ogdensburg, N. Y.—Photographs, etc.
7. Vanderbilt Clinic, New York City.—Photographs, etc.
8. Willard State Hospital for Insane, New York City.—Photographs, etc.

The exhibit having to do with hospitals and insane asylums was large, but, as a whole, not of high character. The displays made usually included merely a few annual reports and a few photographs, which had little practical or scientific value. Little was to be gained by the study of this exhibit as a whole, though a few individual exhibits, as that of Johns Hopkins Hospital, were of a high degree of merit, so far as they went. In making the awards, the jury was desirous of recognizing, among other things, what it regarded as a higher type of hospital report, and for this reason recommended a number of low awards. The jury was impressed with the desirability of the creation of some full collection of material relating to the plans, construction, and management of hospitals and similar institutions, which could be used for reference by those interested. As with a similar collection relating to public health, such a collection should be deposited in the Surgeon-General's Library at Washington, where it would be of benefit to the greatest number.

The following awards were made with respect to surgical instruments, appliances, and supplies:

Gold Medals.

1. Andrews, A. H., Chicago.—Adjustable invalid bed.
2. Belding Bros. & Co., New York City.—Surgical silk.
3. Erickson Artificial Limb Co., Minneapolis, Minn.—Artificial limbs.
4. Kny-Scheerer Co., New York City.—Surgical instruments and appliances.
5. Meyrowitz, E. B., New York City.—Ophthalmological and optical instruments.
6. Marks, A. A., New York City.—Artificial limbs.
7. Seabury & Johnson, New York City.—Surgical dressings and supplies.

Silver Medals.

1. Frees, C. A., New York City.—Artificial limbs.
2. Meyrowitz, E. B., New York City.—Surgical instruments.

Bronze Medals.

1. Alexander, H. M., & Co., Marietta, Pa.—Vaccine virus.
2. Fuller Co., Rochester, N. Y.—Artificial limbs.
3. Pocono Laboratories, Swiftwater, Pa.—Vaccine virus.

In the above class, the number of exhibits was comparatively small. The Andrews adjustable bed is simple and practical, and is probably the best appliance of this character yet brought out. A high grade of artificial limbs was shown. The most full exhibit in this line was made by Marks, but the jury was also favorably im-

pressed with certain features of the limbs made by Erickson. The exhibit made by the Kny-Scheerer Company was complete, attractive, and in all respects admirable. Meyrowitz, of course, made an excellent display of ophthalmological instruments and appliances, while Seabury & Johnson showed a very full selection of their well-known wares.

Among the exhibits of drugs and medicines, the following awards were made:

Gold Medals.

1. Armour & Co., Chicago.—Animal extracts.
2. Larkin Soap Co., Buffalo.—Glycerin.
3. Roessler & Hasslacher Chemical Co., New York City.—Acetone and chloroform.

Silver Medals.

1. Matheson & Co., L't'd, New York City.—Sodium sulphite and hyposulphite.
2. Mathieson Alkali Works, Saltsville, Va.—Sodium bicarbonate.

Honorable Mention.

1. Crescent Silicate Works, New Orleans, La.—Silicates of sodium.

The display of drugs, medicines, and medicinal supplies was very meager, not a single one of the large pharmaceutical firms making an exhibit at the Exposition. A considerable number of articles of this character were shown in the exhibits of the South-American countries, but none of these were in any respect noteworthy. A considerable number of patent medicines were exhibited, both by exhibitors from the United States and foreign countries. All such articles or secret preparations were thrown out of competition by the jury of award, and received no official consideration. This attitude of the jury was not at first understood by foreign exhibitors, who were accustomed to see preparations of this character held in higher estimation in their own South-American countries. A number of vigorous protests on this matter were registered, but without effect as far as the Exposition officials were concerned.

In looking over the situation at the Pan-American Exposition, one is profoundly impressed with the remarkable paucity of the exhibits having to do with the welfare of the individual or the health of the community, as compared with those representing the industrial arts. Evidently, the public is in need of education with respect to the purposes, methods, and responsibilities of the medical profession. Such education should be given at the Louisiana Purchase Exhibition in 1903, a date which permits of the preparation in the meantime of a sanitary exhibit which could be made at once instructive, interesting, and popular, and which, properly installed in sufficient space in a suitable and attractive building, would do an incalculable amount of good in educating the public in respect to matters affecting the general and individual health and welfare. It is to be hoped that this matter may be forcefully presented to the authorities of the Exposition at St. Louis, and that the collection of a sanitary and medical exhibit, extensive and well-chosen, may be at once begun by competent and energetic individuals, backed by sufficient funds to insure success.

A HELP THAT DOES NOT HARM.

To the Editor of the Medical Record:

Sir: A year ago I submitted in these columns a letter setting forth some observations which I had made while inspecting the vacation parties that the New York Association for Improving the Condition of the Poor had sent down to Sea Breeze, their summer place on Coney Island. Once or twice each week during this past summer I again inspected such parties.

As before, the main object was the elimination of contagious diseases. I again saw some of the conditions which I had previously found, but these were certainly mitigated. On hot days I still came upon red-faced, panting infants, with half a dozen thicknesses of clothing bound about them, and the layers, when they were peeled off, would be reeking with perspiration. But these experiences were now comparatively infrequent. Generally, the reason given for all this redundancy was to protect the infant from catching cold. Another reason, I learned, was that clothing is carried easier that way. The mothers themselves and their older children, I am told, wore much superabundant clothing, of which they divested themslves when they got to Sea Breeze. They made of themselves a species of "walking trunks."

It seemed to me that there was not so much irregularity in diet and overfeeding. I imagine that the visiting staff of the association has been doing most useful missionary work in disseminating advice concerning sanitation, infant dietetics, and hygiene generally.

The cases of contagious eye disease were quite as numerous as ever—some 10 per cent. of the children were thus afflicted. Most of these cases were of granular lids. It seems that not infrequently, when such a child complains, the mother will consider the eyes are strained and that glasses are needed. In one case, a kind-hearted neighbor loaned a pair of spectacles which someone else had worn with satisfaction, and these I found the boy wearing. He had granular lids.

In the beginning of the summer there was a rather unusual amount of smallpox in this city. So it was particularly noted whether the children were vaccinated. At first the proportion of unvaccinated children was very large. On one occasion there were in a total of sixty-four children, under six years of age, twenty-two who had never been properly vaccinated. Again, among fifty-nine women and children, fourteen children were unvaccinated. Again, among seventy-three children, thirty-four had never been vaccinated. The proportion of unvaccinated children was so great that to have excluded all such was out of the question.

Almost daily do the steamships bring to our already plethoric city thousands of steerage passengers who carry with them almost ideal conditions for the spread of any contagion. An unvaccinated child should, therefore, be a rarity. Only children under a few months of age should be exempt from this slight operation.

As the summer wore on there was a most gratifying difference in the proportion of vaccinated to unvaccinated children. The change was due, I believe, to the vigilance of the association's visitors, so that on July 1 there were but thirteen unvaccinated children, all of them but a few months old, in a total of seventy-five children, and on July 18 there were but six unvaccinated children, mostly infants, in a total of sixty-seven children.

A pathetic reminder of the prolonged great heat of the summer was the loss of an unusual number of children, whom the mothers deplored.

The association evidenced its usefulness in refreshing aged women, in strengthening others after long periods of illness and misfortune, and in helping to restore to convalescence those who have sustained operations in the hospitals. Again, not a few women were going to Sea Breeze to recuperate sufficiently to undergo operations on their return.

Two mothers, each having several children, evidenced consumption. Their sufferings were for the time being alleviated during their vacation. It will be a great boon when our State establishes sanatoria for such sufferers.

As I think back upon these inspections, I seem to have contemplated a truly Hogarthean panorama. Old women, mothers, and children passed by me in rapid succession; old women who could only guess how old they were and who were suffering from rheumatism, asthma, heart disease, and the like; a lame woman over seventy, whose leg had been broken in childhood; a child with hip disease that had two abscesses draining away its strength; a child who was a cretin; another with a curvature of the spine; a large family of children who came by themselves and whose mother was sick in the hospital; several members of a family, all obviously hysterics; children browsing continually upon cakes; a woman with goiter; an infant of several weeks whose eruptions betrayed the sins of the father; a woman who could not remember whether she had three or four children and had to ask her mother to tell her; a woman who a year ago had had eleven children and, to her deep sorrow, had lost one of them since then; a girl of fourteen who was blind and had been so since birth, when she contracted purulent conjunctivitis, and so on.

Yet there was little of melancholy among these people; indeed, a spirit of general optimism was universally pervasive. They needed the outing very badly, and they anticipated being benefited by it.

It was certainly a pleasure to appreciate this wholesome charity, which is a help that does not harm. It were fortunate, indeed, if this could be said of all our municipal charities.

John B. Huber, M.D.
41 West Forty-fifth Street, New York City.

Anatomy of the Frontal Sinuses.—Sieur has studied various skulls, and concludes that the absence of the frontal sinus is less frequent than is supposed; in fact, in almost a third of the cases this sinus has no relation with the squamous or ascending portion of the frontal bone. The sinus is often small, and occupies the superior internal angle of its orbit, and corresponds to the narrow, thin lamella of the frontal bone which takes part in the formation of this angle. In inflammation of such sinuses the proper route of attack is through the orbit.—*Revue Hebdomadaire de Laryngologie, etc.*

THE USE OF SULPHATE OF COPPER IN AFFECTIONS OF CORNEA AND CONJUNCTIVA.

To the Editor of the Medical Record:

Sir: In your issue of September 21, 1901, there appeared an article by Dr. Cornelius Williams which practically amounted to a critique on an article of mine which recently appeared in your journal, entitled "The Use of Sulphate of Copper in Corneal Affections and in Affections of the Conjunctiva, Other Than Trachoma." In my article I strongly advocated the use of this salt in affections of the conjunctiva, other than trachoma, which are sometimes associated with corneal complications; and also in selected cases of infiltration of the cornea, uncomplicated by conjunctivitis and caused by a preceding corneal disease. A gentleman of Dr. Williams' age and experience is entitled to an opinion of weight. His criticisms, however, upon my own views lead me to reply to this critique in order that I may lay stress once more upon what I think is the scientific truth, and point out to those of less experience what I consider to be a scientific untruth.

Dr. Williams will, of course, understand that this expression of opinion is caused by no other than a desire to arrive at the truth. Those who are of the age of Dr. Williams, have already formed their opinions on the subject, and neither his nor my statement will influence them. But there are other and younger members of the profession, and to them my remarks will be addressed.

Dr. Williams' paper has been taken up mainly with a discussion of the treatment of trachoma—a matter which I strictly avoided, as shown in my title. Dr. Williams, in the first place, recited a case of mixed infection of trachoma and blenorrhea in which there were corneal complications. The patient subsequently was sent to New York and was treated by some one with bluestone. No atropine was used, but the ulcers of the cornea were treated with peroxide of hydrogen. The patient referred to the pain experienced from the application of the bluestone as "infernal." After a month of this treatment he returned home, and his physician found that he had been suffering from iritis, associated with occlusion of the pupil and ulcer of the cornea, which was perforated. Some one, presumably Dr. Williams, operated for glaucoma which supervened; and under the use of weak solutions of nitrate of silver and irrigation with weak solutions of bichloride of mercury the patient got well, with vision of 5/200. Dr. Williams admits himself that the bluestone is not entirely to blame for this disaster, and goes on to say: "I think that even Dr. Claiborne must admit that it was faithfully used by skilled hands." He thought the iritis in this case was excited by bluestone in addition to the corneal complications; and would not have occurred had not both exciting causes been operative.

In this sad story even the youngest ophthalmologist will recognize the misfortune that may come to any one. The quotation used above would intimate that I myself knew something of this case or had treated it. I disclaim any knowledge of it whatsoever. In past years it was my custom following my early instruction to use atropine in every case of trachoma that exhibited corneal infiltration or ulcers. Subsequently, my attention was called to this error by some of the distinguished gentlemen at whose feet I had formerly sat, and I commenced to observe that atropine was not indicated in every case of trachoma as described above. I continued and have always continued to use atropine in those cases in which there is so much as a suspicion of iritis. I think this is good practice, and will be commended by all sensible eye surgeons. There is no earthly occasion for the use of atropine in the majority of cases of trachoma that are uncomplicated by iritis. Its disadvantages are too well known to be recounted here; but I may say that in my opinion its constant use in trachoma retards recovery. I feel that I shall be upheld in this opinion by a large majority of eye surgeons in New York.

From the history of the case, as described by Dr. Williams, I should be inclined to think that iritis was caused by the perforation of the cornea. I conceive this case to prove nothing against bluestone; it is simply a pathetic story. I think there can be no doubt that trachoma has different phases in different portions of the country. When I was studying with Hirschberg in Berlin, I heard him say in a lecture that he cured all cases of trachoma with a 1-per-cent. solution of nitrate of silver. My observation of the trachoma in Berlin at that time led me to think it a mild disease there; and I doubt very seriously the accuracy of the observation, even with the mild trachoma of Berlin. If he should come in contact with the Hibernian trachoma of the lower classes in New York, I believe he would change his opinion. Dr. Knapp's opinion concerning those who fail properly to treat an iritis will be backed up by every surgeon. But Dr. Knapp has never suggested to treat a patient for iritis when there is none. Dr. Williams lays great stress on the congestion, pain, and ciliary spasm which follow the use of bluestone. He goes so far as to suggest congestion of the entire uveal tract. Bluestone to some people is excessively irritating, but if it be applied skilfully, lightly, and the surplus washed off, it produces, in my opinion, no such effect as Dr. Williams describes. I cannot conceive it to produce an iritis. Patients get used to it, and are finally inconvenienced almost to no extent.

Dr. Williams recites another case that to me is simply astounding. He cites the case of a man with trachoma which had been treated by six or eight eminent surgeons. There was entropion, shortening of the lid, scars on the inner surface of the lids, fresh corneal ulcers, and old corneal scars; there was lacrymation and a "running nose." He cured this patient completely by the use of a $\frac{1}{16}$ to $\frac{1}{8}$ of a grain of nitrate of silver solution, and by frequent irrigations with bichloride salt solution, 1 to 40,000. He laid stress on the necessity of cleansing the conjunctiva first. He cured this case in three months. This gentleman communicated the results of his treatment to another family in which there were four persons with trachoma. They were all treated in this manner, and were eventually entirely cured. Such a result as this is, to say the least of it, astounding.

I have no further remark to make upon it except to say that I have never seen such results in my own treatment, nor yet in any one else's.

If Dr. Williams has discovered that trachoma, chronic and acute, can be cured by the use of $\frac{1}{16}$ to $\frac{1}{8}$ of a grain of nitrate-of-silver solution, associated with irrigation of the conjunctiva with a salt solution of bichloride of mercury, 1 to 40,000, he has made one of the most remarkable discoveries in medicine. It is high time that he made it known, and I rejoice that my paper should have called forth this statement. For my own part, I am willing to learn and be convinced of anything; but I should prefer to see these results under Dr. Williams' own hands before I forsake the paths pointed out to me by the eminent authorities under whom I have studied, and along which my own experience has led me, so far, fairly successfully.

J. H. Claiborne, M.D.

39 West Thirty-sixth Street, New York.

Heart Lesions and Pregnancy.—O. Fellner says that with suitable treatment the majority of patients with cardiac disease pass safely through labor, only mitral stenosis appearing to be particularly dangerous. With this exception, it is the severity and not the nature of the lesion that is of importance, and it is particularly the quality of the heart muscle that must be considered. It is the exception for pregnancy to exercise an untoward influence on the heart, and with good compensation, abortion is indicated only when a previous labor was followed by serious consequences; with broken compensation, immediate induction of labor should be done only when internal medication appears hopeless, otherwise the operation should be postponed until the condition has been improved by suitable treatment. Marriage should be forbidden only in cases with marked disturbance of compensation, or in mitral stenosis, and when tuberculosis or chronic nephritis are complications.—*Monatsschrift fur Geburtshulfe und Gynækologie.*

The Climate of the Coast of New South Wales in Relation to Pulmonary Tuberculosis.—W. C. Wilkinson believes that the air of the seacoast of New South Wales, far from being injurious to those suffering from pulmonary tuberculosis in the early stages, is beneficial and may have as much curative virtue as any other climate in the world. In that country there are 500 fewer deaths per 1,000,000 from tuberculosis than there are in England. The climate is mild and equable, being free from great variations in temperature, and with a cool, refreshing northeast wind from the sea supplying relatively germ-free air during the hotter months (from January to April), and during the cooler months with winds that are less severe and more propitious than the cold, piercing winds of the mountains. There is a mean summer temperature of 70° to 75° F., a mean winter temperature of 53.5° F., and a mean annual temperature of 63.2° F.—*Australasian Medical Gazette.*

Progress of Medical Science.

The Boston Medical and Surgical Journal, October 17, 1901

Privileged Medical Communications.—David W. Cheever urges a modification of the Massachusetts law, which differs from the rule adopted in the courts of New York, where the doctor is not only protected, but even forbidden to testify as to his knowledge obtained in a professional capacity. Mental obliquity, cases of conscience, private diseases, hereditary taints, sins of a sexual nature, once committed but long repented of, hysterical fears, questions of inheritance, of mental responsibility, of illegitimacy, of adultery, of suicide, of life insurance, of testaments, etc., should be matters held sacredly in confidence. The doctor should be obliged to speak only in cases of crime, and where justice would miscarry if he refused to tell the fatal secret. Let the criminal court decide, the writer holds, and relieve the doctor of his obligation of secrecy. In all civil suits let him be protected. But in crimes there can be no proper security for society, if the doctor becomes a *particeps criminis* by concealing the truth.

Gangrenous Appendicitis.—Charles L. Scudder reports the case of a woman of twenty-eight years, unmarried, who had always had good health. She was suddenly seized with acute general abdominal pain, slightly more severe in the epigastrium than elsewhere. Since that time there were periods of pain, unprovoked by the taking of food, occurring every second or third day. Vomiting and distention of the abdomen also occurred. This went on for a fortnight. Operation disclosed that the bowel was everywhere adherent to the anterior abdominal wall and to itself. Puriform material was found between the adherent coils of intestine. Over the surface of the gut in many places were dark bluish-black areas, the size of a finger tip, so soft that by very gentle pressure one could penetrate into the intestine. In the left iliac fossa was an accumulation of fecal and of purulent material. The woman lived seven days after the operation. At the autopsy the appendix was found to be gangrenous.

Malignant Disease of the Tonsil.—F. E. Hopkins says that the diagnosis between carcinoma and sarcoma, in these cases, is not always easy. Males are more subject to cancer than females. Epithelioma quickly ulcerates; sarcoma more frequently forms a rounded, smooth, distinct tumor, ulceration occurring later, and beginning at a point which comes in contact with some other surface, as, for example, the base of the tongue. It is stated that carcinoma tends to invade tissues forward, while sarcoma extends backward. The best hope for successful operation lies in early and complete removal. In early sarcoma, operation may be performed through the mouth. To shell out the growth with the finger, or blunt dissection, would seem to offer better promise of thorough removal than the use of the knife or the cautery. Any enlarged lymphatic gland should certainly be removed. At a later stage the external operation is to be performed. Coley treated a case of sarcoma of the tonsils with injections of the toxins of erysipelas. The patient died of recurrence, but after an interval of eight years. Massey has reported cures by the cataphoric destruction of cancer cells. Hubbard successfully treated a case of epithelioma of the soft palate by injections of liquor potassæ.

New York Medical Journal, October 19, 1901.

Social Aspects of Dermatology. In the sixth Lane Lecture, Malcolm Morris discusses the light treatment, mentioning the effect of chemical rays on the skin and giving a full description of Finsen's work. Concerning the prospect of a cure, Morris says that cases that have not been treated are, other things being equal, the most suitable for the light method. In old cases in which the patients have suffered many things from many physicians, the seat of disease is likely to be so deeply scarred by the cauterizations and scrapings it has undergone as to be almost impenetrable to light. If the disease is recent, if there is no scarring or thickening, and if the configuration of the part is such that the pressure-glass can be accurately applied to it (a most important point in practice), there is every reason to look for a thoroughly satisfactory result. If the disease is extensive, the treatment must at the best be tedious. It should be applied daily on six days a week, if there is nothing, as, for instance, excessive reaction, to make interruption necessary. In cases in which there may be a special urgency, the treatment may be carried out twice a day without any ill effect.

The Sanitary Work so far Accomplished in the Philippine Islands and the Present Shape of Their Sanitary Administration. The results of the work are summarized by C. R. Greenleaf of the U. S. Army medical service. The local authorities have had to contend against plague, smallpox, typhoid fever, tetanus, tuberculosis, whooping cough, measles, mumps, and beriberi. The author makes a frank statement regarding the question of dealing with venereal disease, saying that the influx of a foreign population—Asiatic, European, and American—has caused a large increase in this class of disease, which is spreading from the seaports as centers outward into the provinces, and in time a large number of native women will be affected, and with less prospect of cure than their sisters in the cities; the native women outside of the cities are, as a rule, free from disease, but it is they, without opportunity, knowledge, or means sufficient to obtain treatment, who will, when infected, become the greatest sufferers and the greatest menace to the public health. The segregation of this class of women to a certain portion of the towns, a supervision of their health, and a duly recorded treatment of the diseased should be systematically carried out, lest an irreparable injury be done to the people of these islands by those whose duty it is to help and elevate them.

The Advisability of Early Operative Intervention in Acute Mastoiditis.—E. B. Dench claims that in doubtful cases an exploratory incision upon the mastoid is perfectly justifiable. The fact that patients sometimes recover without operation does not in his opinion militate against the truth of his main proposition. He believes that whenever there is an inflammation within the mastoid cells sufficiently severe to cause a fluctuating postaural swelling, operative intervention is invariably indicated and spontaneous recovery is absolutely impossible. Under aseptic precautions the opening of the mastoid is devoid of danger. Delay in a doubtful case may lead to the most serious complications. An otitic brain abscess may remain latent for a long time, but may be excited into renewed activity by some recent infection, such as an acute inflammation of the middle ear. It seems not improbable, therefore, that when we have an acute purulent otitis media, some of the microorganisms may find their way into the mastoid cells. Here they may lie dormant for some time, or they may at first give rise to symptoms indicative of a mild mastoiditis. Under proper local treatment all of these symptoms may subside and the germs may lie dormant for an indefinite period. From some exciting cause, leading to a congestion of the tympanic mucous membrane, these germs may again become virulent and capable of infecting the deeper structures of the mastoid. For this reason he believes that in every case in which there is any evidence of mastoid involvement, it is safer for the patient that the surgeon should advise immediate operation, simply for the purpose of exploration, rather than attempt to abort the inflammatory process by the local abstraction of blood, the application of cold, and kindred measures.

Journal of the American Medical Association, Oct. 19, 1901.

Some Considerations Regarding the Hygiene of Early School Life.—J. Noer utters a vigorous protest against the assumption on the part of certain modern educators that many of the points insisted upon by physicians in regard to school hygiene are matters of psychological pedagogy, and must be settled by the pedagogues themselves. He claims that physiological studies show that the child is an exceedingly immature and delicate animal, undergoing important developmental changes having no analogues in the adult, and that his plastic tissues and delicate nerve cells are easily warped and injured by long-continued mental or physical efforts. Children have actually been injured by injudicious school work, and for this and other reasons physicians should favor shorter hours, more attention to the physical side of the child, more nature study out of doors in contact with actual natural objects, less of textbooks, and less of the exhaustive rote drill, which simply burdens the memory. Pedagogues disagree among themselves on many of the points at issue. It is therefore absurd to leave the question solely to their own decision when they are without well-formulated plans. Regular periodic medical inspection, which should include physiological and anthropometric examination of the school children, should be a requirement in all public schools. These examinations would not only furnish valuable physiological and anthropometric data, but would disclose cases of infectious and other communicable diseases. They would also detect mental and physical defects—stigmata—not readily recognized by parents and teachers. The children with marked mental and physical abnormalities, developmental defects, or stigmata should be segregated for special training. Every town with a school population of from 500 to 1,000 will have a sufficient number of children of this sort to fill a room, which should be in charge of a person having the exceptional qualifications necessary for success in work of this kind.

American Medicine, October 19, 1901.

Purpura Hæmorrhagica Following Acute Lobar Pneumonia.—H. L. Underwood reports the case of a boy aged four and a half years whose convalescence from pneumonia was followed by an attack of persistent epistaxis. The stools also showed that hemorrhage from the bowels had occurred. Purpuric spots were numerous on all four extremities, chest, abdomen, and back; also on the hard and soft palate, lips, and dorsum of the tongue. The face was almost clear. Fluid extract of ergot was ordered, together with syrup of calcium hypophosphite and protonuclein. Again epistaxis set in. Iron, manganese, and Fowler's solution were given. There was exfoliation of the epidermis. An ulcer formed on the side of the tongue. Within two months after the onset of the attack of pneumonia, the patient had made a good recovery.

The Practical Value of Blood Examination in Medicine and Surgery.—Thomas R. Brown declares that in most cases, the examination of a fresh specimen of blood will show whether the blood is normal or abnormal, and in the latter case will indicate the special direction for further study. The diagnosis of malaria and its differentiation from typhoid fever, from syphilitic or gonorrhœal intermittent or remittent fever with chills, can be clearly made by blood examination. Certain forms of primary anæmia can be diagnosed only by blood examination. Lymphatic leukæmia can by this means be diagnosed from Hodgkin's disease, tuberculous or syphilitic adenitis, and sarcomatosis of the glands, while splenomyelogenous leukæmia is differentiated from Banti's disease, chronic malaria with enlarged spleen, tuberculosis, syphilitic or malignant growths of the spleen, hydronephrosis, or renal or ovarian neoplasms. Trichinosis can be definitely diagnosed. In diabetes, the Williamson test is of great value in the diagnosis of cases of coma with anuria. The study of leucocytes has been productive of most valuable results. In surgery, systematic blood examination is of no less importance. Leucocyte counting is of inestimable value in appendicitis. The field of this work is very large. It offers valuable information regarding the prognosis in all forms of infection and inflammation. It is of great value in showing whether the pathological process is increasing or diminishing. It is a field for practical men as well as for theorists.

Philadelphia Medical Journal, October 19, 1901.

A Case of Transplantation of the Ureter for the Cure of Ureterovaginal Fistula.—A. Lapthorn Smith reports the case of a woman aged thirty-four, who was suffering from a ureterovaginal fistula, resulting from a difficult labor. The patient had undergone several previous operations without success, so the writer resorted to radical measures and opened the abdomen. Owing to several conditions he was obliged to open the peritoneum to find the ureter. About one inch of its lower end had to be sacrificed; a silk ligature was pulled taut about it, and this end was cut off a little above the ligature and covered with a gauze sponge, as urine came from it. The end of the ureter was split open for a third of an inch, in order to avoid subsequent stricture. A slit was made in the right upper corner of the bladder, and the ureter was stitched into it. Van Hook's method was employed. The bladder was then distended with methyl blue solution and there was found to be no leakage. A drainage tube was passed down from the edge of the abdominal incision to a little below the bladder opening, and a piece of iodoform gauze was inserted down to the lowest point between the peritoneum and the pelvic fascia. The patient has made an excellent recovery.

The Co-ordination of Respiratory Movements.—R. du Bois Reymond declares that if the origin of nervous excitation in respiratory function is not purely automatic, it must be reflex in nature. These reflexes are, first, want of oxygen and excess of carbonic oxide in the blood; the second reflex action on the respiratory centers is purely nervous, comprising the inspiratory and expiratory effects of the vagus nerve and all like reflexes. Since respiratory movement is brought about by many different muscles widely separated and acting together in separate, more or less clearly defined groups, the question of co-ordination of movement is most important. This co-ordination of movement must be due to co-ordinate action of the groups of motor cells corresponding to the different muscles. Certain experiments have been conducted in the investigation of this subject which show that when the animal has ceased to breathe, and artificial respiration has been resorted to, the glottis presents regular accessory movements synchronous with the artificial respiration. These movements were not caused by the direct mechanical influence of the manipulation; nor were they caused mechanically or reflexly by the passage of air through the glottis. Again, all known sources of excitation of the respiratory centers have been excluded by the conditions of the experiments which have been conducted, viz., complete apnœa and complete pneumothorax (or, in several cases; section of the vagus below the origin of the recurrent nerve). So the phenomenon must be due to a hitherto unknown kind of reflex. Further experiments show that the respiratory movements of the larynx are dependent, at least in part, upon the excitation of the muscular sense or posture—perceptive sense of the thorax. Thus the co-ordination of respiration is in this case shown to be exactly analogous to the co-ordination of different muscles in the motion of the limbs. It is probable that the other separate parts of the respiratory mechanism are linked together by similar reflexes. The experiments prove that artificial respiration acts as a direct stimulus, at least on the laryngeal motor center, and probably on other respiratory centers as well.

The Lancet, October 12, 1901.

Cancer, Its Nature and Its Treatment.—John Holden Webb declares that cancer is not communicable, and yet is autoinfective. Cancer is uncontrolled proliferation of the cell. Cholesterine in the economy is in solution, and is kept in this condition by its natural aqueous solvent—soap. It is the loss of this soap that permits cholesterine to separate from the living cell, and cell-cancer to start. The uncholesterine cell is the uncontrolled cell. Cholesterine is at fault in this disease as the bad odor shows. As treatment, the writer uses injections of soap. A bit is dissolved in boiling distilled water and strained. Never more than a teaspoonful should be administered at a time. When thyroid is not contraindicated, it is given per os. This treatment has met with excellent success. When the soap injection is given even alone, pain and odor have been avoided in most trying cases, such as cancer of the tongue. The writer defines malignancy as the crystallization of cholesterine from the living cell.

Mucin in Desiccation, Irritation, and Ulceration of Mucous Membranes.—W. Stuart-Low states that mucin acts by supplying what is deficient in abnormally dry mucous membranes—that is, mucus. He gives it in doses of five grains with an equal amount of sodium bicarbonate. One of the leading clinical indications for its use is the presence of a clean, red, angry, or dry tongue, often a clean, red, fissured tongue, indicating a deficiency of gastric protective coating. With this condition is often associated, a pale and thin, or a pale, thin, and desiccated state of the mucous membrane of the nose and pharynx, or a semi-secretionless post-nasal and pharyngeal surface, and obstinate constipation. If the tongue is rather coated and dry, than red, and there is pain after taking food, and constipation, a saline aperient is indicated to clear away the old gastric mucus and prepare the way for mucin. Peptonized foods are avoided in cases of gastric irritation, erosion, or ulcer. Mucin has a laxative action. It probably aids in protecting the stomach from self-digestion. Besides being used for these affections, it is used as a douche for dry nasal membranes.

A Remarkable Case of a Foreign Body Impacted in the Rectum.—A. Marmaduke Sheild reports this case. The patient was a man aged sixty years. Four days before he asked for treatment, he had forced a gallipot (about the size of a Dundee marmalade jar) up the rectum. He had passed some loose stools since, and there was no great pain or difficulty in micturition. The patient had attempted to remove the pot and had broken it leaving several jagged edges. An anæsthetic was given the patient, and the broken edges of the pot could just be felt by the index finger. These points were imbedded in swollen and prolapsed mucous membrane. The operator made a free incision in the bowel posteriorly down to the coccyx behind, the bistoury being entered above, close to the foreign body. By using a short-bladed pair of obstetric forceps, with careful traction and "swaying" movements, the mass was brought into the large wound and extracted. The wound was closed, but soon became very septic. The stitches were removed, the wound was lightly plunged, and a warm boric hip-bath was employed. The patient made a good recovery.

The Present Treatment of Inoperable Cancer.—Alfred Cooper concludes: (1) That in cases of inoperable sarcoma, more especially the spindle-cell variety, the patient should have the option of Coley's fluid given to him, since a certain number of cases have been cured. (2) That in cases of inoperable cancer of the breast in women of about forty years of age, in whom the menopause has not occurred, the operation of oöphorectomy should be proposed, and this treatment may be combined with

thyroid feeding. (3) That in cases of inoperable rodent ulcer and of superficial malignant ulceration in other parts, the Röntgen rays give a good hope of improvement. (4) That in cases in which these other methods are declined or are inapplicable, the internal administration of celandine is worthy of trial, and when the case appears quite hopeless, morphine should be pushed without hesitation. (5) Finally, the writer suggests that before trying any of these remedies the risk should be fully pointed out to the patient, that the faint hope that most of them afford should not be magnified, and that the discomfort of treatment should be fully discussed; in fact, the surgeon should not do more than offer the treatment and leave the person to accept or reject it.

Berliner klinische Wochenschrift, September 30, 1901.

Renal Tumor in a Child of Six Months.—A. Schonstadt says that tumors of the kidney are relatively frequent in childhood, but that it is rare to observe them in infants less than a year old. His patient was a boy of six months, from whom an adenosarcoma the size of the fist was removed by a lumbar incision. Difficulty was experienced with the narcosis, but the child recovered speedily, and now, seven months after operation, is doing well, with no signs of recurrence.

Gastric Splashing and Atony.—B. Stiller vigorously opposes the dicta of Elsner, who recently deprecated the value of gastric succussion as an indication of atony. According to Stiller's views, there may be atony without muscular insufficiency, and this may be a forerunner of gastroptosis, which condition Elsner admits greatly favors the production of the splashing sound. Stiller therefore argues that the presence of this sign means both ptosis and atony, and says that this triad forms the most constant symptom of nervous dyspepsia. Atony of the stomach means a relaxation of its musculature, which leads to impaired contractility, dilatation, and depression of the lower limits of the organ, with ultimate ptosis. In pure atony only the tonic contraction, and not peristalsis, is defective, but this also becomes gradually impaired so that complete motor insufficiency and gastrectasia may, but does not necessarily, occur. Only rarely is atony a purely local condition dependent on regional causes. In most cases it is due to atony of the entire organism, which leads to enteroptosis, nervous dyspepsia, and general neurasthenia. Such a condition may be called *asthenia universalis congenita*, and of this the atony of the stomach is the most constant sign. The presence of splashing is of the utmost importance as indicating the presence of such a nexus, and its value as a diagnostic aid cannot therefore be underestimated.

Apparent and Actual Disease Foci.—Buttersack says that the prevalent view of the bacteriological origin of disease, which assumes that a given organ is invaded by the organism, and then becomes the seat of disease, is not wholly satisfactory. In the case of viscera, like the lungs and intestine, which have a direct connection with the outer world, the proposition seems tenable and the occurrence of pneumonia, typhoid fever, and pulmonary tuberculosis is explicable on such grounds; but when we come to enclosed structures, like the pleura, pericardium, and joints, to say nothing of the spleen, testicle, or spinal cord, some elaboration of the theory is necessary. Accordingly, the author suggests the lymphatic structures of the body as representing the centers where disease germs congregate and are either disposed of or else sufficiently overcome the forces of the body to make further invasion along the lymphatic channels possible. It is only in this way that it is possible to explain why in typhoid fever, for example, the bronchial lymph nodes, as well as the intestinal ones, are affected, or why it is nearly always the lung, and not the larynx, that is first attacked by the tubercle bacillus, instead of the reverse, which would seem more natural if infection were simply due to inhalation.

Munchener medicinische Wochenschrift, October 1, 1901.

A Case of Pseudoleukæmia with Intermittent Fever and Glycosuria.—A. Goldschmidt's patient was a man of sixty years who, six years ago, developed glandular swellings in the neck and axilla which were diagnosed as due to pseudoleukæmia. After a period of two years, during which the general condition became gradually worse in spite of energetic arsenical therapy, intermittent fever, accompanied by a glycosuria of variable degree, set in and persisted for several months. The condition then improved and remained good until the winter of 1901, when the leucocytes began to increase and the pseudoleukæmia gradually developed into a true leukæmia, which terminated fatally a few months later.

A Foreign Body in the Nose.—Gross was called to see a boy suffering from an intensely fetid discharge from the left nostril which had persisted for over two years and produced deep excoriations about the upper lip and nostril. The right nostril was found clear, but all attempts at examination of the left side were so painful that for eleven days the treatment consisted solely in cocainization and the introduction of swabs charged with argentum Credé. At the end of this time it was possible to introduce a speculum and diagnose a large rhinolith. Under chloroform this was removed with a curette, and the severe hemorrhage which followed was controlled by packing with hydrogen-peroxide gauze. On breaking open the rhinolith it was found that the nucleus consisted of a shoe button which the patient confessed to having introduced four years previously. The author's comment is that every foreign body should be removed from the nose at once, and that a unilateral fetid discharge from the nose of a child always means a foreign body.

Diplococcus Semilunaris, an Accompanier of Tuberculosis.—E. Klebs describes an organism which he has so often encountered in connection with tuberculosis as to cause him to attach importance to it. It is found in the tonsils of tuberculous patients, and its occurrence in greater or less number in these regions gives an idea of the powers of resistance of the patient; when present in abundance, it indicates a less favorable prognosis and diminished capacity of resistance. It is observed not only in pulmonary tuberculosis, but also in bone and joint disease as well as in tuberculous skin lesions, and it may possibly have something in common with the organism described as the germ of articular rheumatism. It also has a relationship to vesical catarrhs and is observed with great frequency in the body of the house fly, from whose crushed head it may easily be obtained in pure culture. Its pathogenic powers are shown by the author's experiments, in the course of which he was able to produce fatal cellulitis in rabbits by the injection of the organism. Its occurrence in man is illustrated by the description of two cases in which it accompanied tuberculous adenitis and pulmonary tuberculosis. The significance of such mixed infections is very marked in tuberculous bone and joint lesions, which become rapidly progressive when the diplococcus semilunaris is present in large numbers.

Deutsche medicinische Wochenschrift, October 3, 1901.

A Special Form of Stenocardia (Pseudostenocardia Rheumatica).—G. V. Voss reports two cases of what at first sight appeared to be angina pectoris, but which on closer analysis resolved themselves into a rheumatic complication. In both instances there was marked tenderness of the muscles of the back which yielded to firm massage, while the pectoral pain seemed due to the involvement of the intercostal muscles.

The Treatment of Anthrax.—J. F. Schultze's patient was a butcher who became infected while skinning a cow, afterward discovered to have died of anthrax. Nine days later a small pustule developed under the left eye, which rapidly became swollen and soon involved both eyelids in an intense œdema. The original pustule formed itself into an ulcer with indurated edges, the pulse ran up to 140, albumin with hyaline and granular casts appeared in the urine, and the œdema rapidly extended over the whole face and neck. In the course of the next few days the temperature went up, there were severe dyspnœa and delirium which persisted till the eighth day, when defervescence occurred, and a line of demarkation formed about the necrotic areas. At the end of six weeks the patient was discharged after a plastic operation had been done to correct ectropion. The site of the disease, almost directly involving the eyes, did not permit of radical measures of any sort, and the only treatment consisted in local applications of alcoholic bichloride solution (1-1000) with five grains of quinine every three hours during the febrile period, and several five-grain doses of naphthalin given for the diarrhœa.

Prosthetic Subcutaneous Injections of Paraffine.—A. E. Stein reports very good results from the subcutaneous injection of paraffine for the purpose of replacing defects following various forms of trauma or disease. Missing testicles or defects due to accident or cicatricial contraction can be replaced in this way with good cosmetic result, and incontinence of urine or fæces due to damaged sphincters can be wholly relieved. The two points that require consideration are the possible toxic effects that may be produced by the slow absorption of the mass from the tissues, and whether pulmonary embolism can occur through the entry of the still-fluid paraffine into the blood current. The author's experiments show both of these dangers to be minimal; for in mice one-third of the body -

weight of paraffine could be injected without bad effects, while in a very large number of injections no pulmonary symptoms developed. The mass to be employed should be absolutely sterile and have a melting point of from 42 to 43° C. If the melting point is much lower than this the proper form is not retained, and if it is too high, local irritation is produced, often ending in gangrene. In favorable cases it is probable that the mass is invaded by a gradual fibrous ingrowth from the surrounding parts, giving it permanence and firmness. Not more than about a gram should be injected at a single sitting. The operation is not painful, and the patient usually is not kept from his work. Several photographs show good results in cases of saddle-nose and cleft palate.

French Journals.

Obstetrical Stigmata of Degeneration.—Larger declares that all of the anomalies of conception, of pregnancy, of labor, and of the fœtus are signs of degeneration. In this class he includes sterility, extra-uterine pregnancy, monstrosities, abnormal presentations, and all alterations in the fœtus, placenta, membranes, or amniotic liquid. These stigmata may be transmitted by heredity in the original form, or they may be transformed by heredity into other kinds; for example, mental or physical stigmata can be transformed into obstetrical stigmata, and *vice versa*.—*La Presse Médicale*, October 9, 1901.

Signs of Tubal Pregnancy.—Martin insists particularly on the colicky pains resembling uterine pains, and on the continuous discharge from the cervix. He shows that besides those cases in which rupture of the tube occurs, with flooding of the peritoneum, there are others, perhaps more frequent than the first, in which the phenomena are less striking, and which have to be observed most carefully in order to establish the diagnosis. He draws a parallel between tubal abortion and uterine abortion.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, October 10, 1901.

Enucleation of Uterine Fibroids.—Albert Martin believes in conservative surgical treatment of these tumors. In patients who are not pregnant, he gives the following advice: If the tumor is a sub-mucous fibroma, dilate the cervix and enucleate the tumor piece-meal; if the tumor is subperitoneal, multiple or not, practise laparotomy, and enucleate the fibroid *en masse* or in two parts, and then close the uterine wound. Finally, it is only in those patients with multiple or very large interstitial fibromata that it is necessary to resort to total or nearly total abdominal hysterectomy, and in case of doubt as to the position and the exact connections of the tumor, one must always try to do first a myomectomy by the abdominal way, as by this method alone can a clear insight and judgment be obtained. In the case of pregnant women, surgical intervention should be resorted to only after the most careful thought and consideration. In cases of dystocia from a uterine fibroma, cæsarian section followed by conservative myomectomy is the operation of choice, total or partial abdominal hysterectomy being undertaken only as an operation of necessity.—*La Revue Médicale de Normandie*, October 10, 1901.

Arrhythmical Hysterical Chorea of Childhood.—G. Carrière and F. D. Sonneville state that, according to Pitres, all hysterical manifestations have five distinct characteristics: (1) They are the result of purely functional troubles of the nervous system. (2) They can be suddenly called forth, modified or suppressed by psychical influences or by physical causes which have no influence on similar phenomena dependent upon organic lesions. (3) They are rarely isolated, certain of the latent stigmata coexisting with the striking manifestations of the neurosis. (4) They have no regular evolution, occur without preëstablished order, and take place under different forms and at different periods in the same subject. (5) They have not habitually the same influence on the general health and on the mental state of the individuals afflicted, as similar phenomena dependent upon another cause. It cannot be stated positively that arrhythmical hysterical chorea is not associated with organic lesions, for, as far as the authors are aware, there has never been an autopsy on such a case. The reason why they believe that this affection is not connected with organic lesions is the rapidity with which these movements are cured and disappear under the influence of any suggestion whatever. What organic lesion disappears thus under such circumstances? It is a fundamental characteristic of hysterical phenomena to be called forth, modified, or suppressed by external manœuvers, or by psychical causes. Arrhythmical hysterical chorea of childhood is indeed only a form of hysteria.—*Archives Générales de Médecine*, October, 1901.

Therapeutic Monthly, September, 1901.

The Treatment of Exophthalmic Goiter with Special Reference to the Use of Sodium Phosphate.—Joseph Sailer concludes from his experience with two cases that in those instances (probably the majority) in which operation for one reason or another is considered inadvisable, sodium phosphate offers at present the best means at our command for relieving the patient. The dose appears to be from about one drachm to one-half ounce daily, guarded, if necessary, by some mild astringent, such as aromatic sulphuric acid.

Caribou or Water-Buffalo Virus.—Charles A. Cattemole says that he has had evidence, from a case observed in the Philippines, that an attack of variola does not invariably protect the subject from vaccinia with caribou virus. It cannot be said, however, that this individual would not be protected from another attack of variola. There is no essential difference in the course of vaccinia with caribou virus and that produced by bovine virus. The former seems to be the more potent, and is more resistant to the deteriorating effects of a hot climate.

The Therapy of Pulmonary Tuberculosis; A Study of Some Forms of Medical Treatment.—Thomas Luther Coley draws the following conclusions: 1. That there is no specific treatment for pulmonary tuberculosis. 2. That the most satisfactory results of treatment can be accomplished only when a careful and repeated study has been made of the patient's powers of digestion and assimilation, and when these are kept at the highest possible point of efficiency. 3. That the action of tuberculin is unquestionably beneficial in a certain percentage of incipient cases. 4. That of the so-called antitoxins some may possess a little antitoxic power, but scarcely sufficient for curative purposes in the vast majority even of incipient cases of tuberculosis, either in man or in animals. 5. That the treatment of pulmonary tuberculosis with antiseptics has not yielded especially favorable results. Antiseptics administered internally are of value largely on account of the action on the gastrointestinal tract. Intratracheally, or intravenously, or by atomization, they are of no appreciable value. When given by inhalation, they are of value only on account of the possible deterrent effect on secondary infection. To secure the best results from inhalation, Ruata's method, while heroic, seems the most logical, but is difficult of attainment in the majority of cases.

The Climatic Treatment of Tuberculous Consumption.—T. Mellor Tyson believes that cases of early apical affection and little constitutional disturbance are most benefited by altitude. Cases with more advanced disease, showing some consolidation, but no excavation or any serious disturbance, do well. When both the apices are inuolved, or much of one lung, and the temperature is generally over 100° F. (37.7 C.), it is best to begin with a low altitude. Hemorrhagic cases, early cases with hæmoptysis and without fever or extensive lesions, are benefited. Patients with advanced disease, those with cavities or severe hectic symptoms, should not be sent to high altitudes. A small, quiet cavity is not a contraindication; hectic symptoms are a contraindication. Patients in an acute condition should not be sent. Cases of fibroid phthisis are not suitable. Convalescents from pneumonia or pleurisy are usually well suited for elevated regions. Advanced cases of tuberculous laryngitis, if good local treatment and freedom from dust can be had, may do no worse than elsewhere. In cases complicated by other diseases there is much care needed. Cardiac dilatation precludes high altitudes; so also does hypertrophy for the most part, though with exceptions. A cardiac murmur, the result of old endocarditis, with no signs of enlargement or deranged circulation, should not deter. Nervous derangements of the heart are usually contraindications. In renal disease, and in chronic hepatitis, the local physicians claim that benefit is often obtained. Intestinal ulceration is not barred out, but benefit is doubtful. Heredity to phthisis does not contraindicate high altitudes. Diabetes is a contraindication. Syphilis is no contraindication, though the combination with phthisis always makes the prognosis bad.

American Journal of the Medical Sciences, October, 1901.

Influenza as a Causal Factor in Acute Mastoiditis and the Early Treatment.—James Francis McCaw emphasizes the fact that in influenza we get two distinct types of tympanomastoiditis: First, the suppurative, which invades the tympanum, antrum, and cells almost simultaneously in an unusually virulent and destructive process, which calls for early surgical treatment, and in which abortive measures are contraindicated. Second, the hemorrhagic, with very pronounced symptoms at first,

but which yields readily to abortive measures, and, in the writer's experience, only about 5 per cent. go on to suppuration requiring radical interference.

A Case of Malarial Nephritis, with Massing of Parasites in the Kidney.—James Ewing states that microscopical examination of the kidneys of fatal cases of malaria has yielded evidence of three main types of acute renal lesions occurring in this disease: 1. Acute degeneration of toxic origin, often reaching a degree in which exudation of blood serum into the tubules is added. This lesion is responsible for the vast majority of the cases of albuminuria in malaria. 2. An extreme form of acute degeneration, with focal necroses, numerous hemorrhages, and exudation into the tubules of blood serum and blood pigments. This lesion is seen in cases of hæmoglobinuric malarial fever, and it has not yet been found associated with an excessive number of parasites in the capillary vessels. 3. Massing of parasites in the renal capillaries, with extreme degeneration of parenchyma cells, multiple hemorrhages, and exudation of blood serum into the tubules. It seems certain that this type of lesion can occur only in severe estivoautumnal infections. There is anatomical evidence that in the pernicious estivoautumnal cases the three types of lesions may be variously combined, but no good reason for believing that with the benign tertian infection occurring in this latitude any other than the first type can exist.

The Journal of Tropical Medicine, October 1, 1901.

Influence of Color on Mosquitos.—Osborne Browne has observed that mosquitos seek out dark places to retreat to in the intervals of their attacks, and holds that walls, furniture, etc., should be of a light color. He believes that to fight them one should pay attention to details, screen windows and doors, open the house to sunshine and fresh air, brush ceilings, corners, and behind furniture daily, put all dark clothes away, kerosene the tanks, keep natives (on the Gold Coast) at a distance, paint houses white, use a good net hung within the poles of the bed, thrown up during the day and personally tucked under the mattress at night, use light-colored clothes, and avoid late dinners with friends. He does not believe that upturning the earth frees resting spores.

The Geographical Distribution of Bilharzia.—W. G. Tottenham Posnett holds that the distribution of this parasite is of much greater extent than is generally supposed, and reports two cases seen in the hospital at Bloemfontein. He believes that 80 per cent. of the cases of so-called hæmaturia that have occurred among the troops in this campaign have been due to bilharzia. It is not surprising that a large number of cases should occur when we consider that the thirsty troops after a hard march, in the great majority of cases have nothing to drink but the water contained in the dams of farms, or a "water hole." It is very probable that we shall find that this parasite is distributed throughout the African continent.

The Danger of Subcutaneous Injection of Quinine.—R. M. Townsend invites discussion on this matter, having had some troublesome cases of abscesses and necrosis over the site of injection, although there was careful sterilization of syringe, solution, and skin, and injections of strychnine produced no signs of inflammation whatever.

James Cantlie asks why, if hypodermic methods of treating malaria by quinine are as effectual, simple, and beneficial as enthusiasts claim, they are not in more general use? He has been prejudiced against its use by seeing the results in the practice of other medical men. In Hong Kong, five or six persons came to him with abscesses on the outer aspect of the left forearm. They had all been treated by subcutaneous injections of quinine for malaria. The abscesses were large, deep, troublesome, very slow in healing and left a permanent and unsightly scar.

Ankylostomiasis in South China.—J. Preston Maxwell holds that a great many of the obscure so-called "malarial cachexias" of the sub-tropical region of which he writes will turn out, on fuller examination, to be cases of ankylostomiasis. Three classes of patients are affected with this parasite: 1. Those in whom it is the sole disease, whose anæmia is due to the parasite and in whose stools are many ankylostomum ova. 2. Cases in which the disease is complicated by malaria, phthisis, Bright's disease, or other malady. 3. Cases in which, so far as one can judge, the presence of the parasite causes little trouble, and would not be suspected were it not found on casual examination of the stools. The disease is, however, not innocuous. In the treatment, the first thing to be done is to clear out the round worm by santonin, followed by a sharp purgative. Thymol (gr. x) given every second night for three or four times, followed by castor oil in the morning, will bring away the ankylostomes, but very slowly. A specific easier of administration and causing less depression would be a boon. The diet should be rich, but easily digested, and in tropical countries the combination of quinine with the iron given is a great advantage.

The Scottish Medical and Surgical Journal, October, 1901.

Skin Grafting by the Wolfe-Krause Method.—H. M. & W. Gray reports nine cases. The method consists in the transplantation of strips or pieces of the entire thickness of the skin, thus differing entirely from Thiersch's method, in which strips of epidermis are shaved off, usually from the front of the thigh. The author describes the technique, and says that he considers the process preferable to Thiersch's, because it gives a more natural-looking, more resistant, and less contractile surface in a shorter time. The method is also easier to carry out. The grafts are most successful when placed on clean-cut, freshly vivified areas of normal tissue; less so on scraped granulating surfaces. It is wise, therefore, to procure, whenever possible, a basis of freshly vivified healthy tissue, by excising widely the pathological part for which the grafting is to be done. When this is impossible without resulting in increased loss of function in the case of granulating surfaces, probably Thiersch's method will give better results.

A Case of Musculospiral Paralysis Following Separation of the Lower Epiphysis of the Humerus; Recovery After Operation.—Robert Purves reports the case of a boy of five years, whose left arm after fracture was placed in splints for seventeen days. When the splints were removed, the wrist was flexed and the hand could not be raised. The author operated, exposing the nerve between the supinator longus and the brachialis anticus, and the nerve of supply to the supinator was seen entering that muscle. The main trunk was followed down to the edge of the diaphysis, at which point it became narrower, and was firmly adherent to the periosteum. On tracing it farther, it was found to dip over the projecting edge of the diaphysis into the hollow beneath, and was closely bound down to the line of separation of the epiphysis. It was freed from the fibrous tissue investing it, and followed to its point of bifurcation. The periosteum over the end of the shaft was then pushed aside, the sharp corner rounded off, and the periosteum replaced and sutured. The nerve, which was exceedingly attenuated, was laid in a new channel to the outer side, and the wound closed. After ten days, the wound being healed, massage and electricity were applied daily. Recovery was complete. The child remains left-handed, though for five months he was dependent on his right arm alone.

Wound of the External Iliac Artery Treated by Suture.—J. Hogarth Pringle describes the case of a man who had received a wound of the external iliac artery on the anterointernal aspect of the vessel, the wound being one-quarter inch long, and running rather obliquely to the axis of the artery. The aorta was compressed, while a clot was removed from the wound in the artery, and then catgut sutures were inserted. A decided kink was produced in the artery, but there was no leakage when the aorta was released. The wound was situated about one-quarter inch above the origin of the deep circumflex iliac, which was tied. The wound healed aseptically. Six months later the patient assented that the limb was "as strong as ever it was," and there was no sign of any yielding of the arterial coats, no sign of hernia, no atrophy of the limb, while the measurement at the widest part of the thigh and the calf was the same on each side. Where successful suture of a large artery is possible (by successful is meant the preservation of the lumen of the vessel), it will probably be more satisfactory than ligature. The risk of gangrene is reduced to a minimum; there ought to be no wasting of that segment of the body to which the vessel is distributed, and the peculiar sensation of weakness and the vague pains complained of for long periods after ligation of an artery in continuity may possibly be avoided. The chief factor for success is asepsis.

Edinburgh Medical Journal, October, 1901.

Volcanic Action as a Cause of Outbreaks of Epidemic Disease.—N. Bardswell has made a careful study of this question and brought to light many interesting facts. He confines his attention mainly to the effects of earthquakes which often disturb water and drainage pipes, thus leading to leakage with all its dangers. The health records of various localities show that following severe earthquakes we may expect a marked increase in typhoid fever. Other localities show under similar conditions a marked increase in the prevalence of malaria and choleraic diseases. Again, epidemics of neuroses are very common. These may consist of functional disturbances, such as nausea, vomiting, headache, vertigo, diarrhœa, frequent

micturition, hystero-epilepsy, disordered sensations, etc.; of various abnormal mental conditions (apprehension, depression, prostration, moral instability, and loss of control, mania, and insanity), or there may be a functional paralysis, as paralysis of limbs or railway spine. Other diseases which seem to have followed upon the trail of earthquakes are conjunctivitis, keratitis, tetanus, and erysipelas. The article contains much valuable information and will doubtless be often referred to in coming years.

The Means of Arresting Acute Endocarditis.—Richard Caton advises absolute physical rest for at least six weeks. The patient is kept in bed with the head low; he is not permitted to raise himself, nor leave his bed for any purpose. Sleep is encouraged, pain and also all mental excitement are avoided, the diet is simple and unstimulating. Salicylates are to be given, but they do not do as much for the heart as for the joints. There is no evidence to prove that they prevent or remove endocardial affections. The heart tonics, such as caffeine, digitalis, and strophanthus, appear to exert an injurious rather than a beneficial effect. We must excite the trophic centers of the heart to increased effort in the attempt to combat the rheumatic poison. With this end in view, a succession of small blisters is applied to the wall of the chest, between clavicle and nipple; each blister is followed by a small poultice. If the application is made in the proper manner, scarcely any pain or inconvenience is complained of by the patient, even in the case of children. In the course of the disease, structural changes take place in the valve cusps, or the considerable amount of imperfectly organized material which is effused into the substance and upon the surface of the inflamed cusp. If complete restoration is to take place, it is essential that this effused material should be absorbed and removed as soon as possible. It seems, therefore, wise to administer one of those drugs which are believed to absorb effusions and remove thickening in fibrous tissues. Of these, sodium iodide seems the most suitable; it is consequently given. The iodide may also be of service, along with a restricted diet, in lessening the volume of the blood. From a large experience with the disease in question, the author draws the following conclusions: (1) If the cardiac complications of acute rheumatism receive no special treatment, and the patient is allowed, when the rheumatism has subsided, to return to his usual course of life, he will, in the great majority of cases, become the subject of organic heart disease. (2) In all cases of acute and subacute rheumatism, and in the obscure cases of rheumatism peculiar to childhood, it is important to keep a close watch upon the heart, so as to detect the onset of valvulitis in the early stage. (3) If the disease is early detected, and is then judiciously treated, in a large proportion of cases organic mischief will be averted.

Intermenstrual Dysmenorrhœa.—A. M. Watson reports a case of this nature, the patient being thirty-six years of age. Menstruation was always regular and painless, and the amount was not excessive. The intermenstrual pain dated back to the birth of the last child, five years before, and came on fourteen days after the close of a period lasting for three days. The spasms were like those of ordinary dysmenorrhœa, but there was no discharge of blood or of other fluid. Constipation, always present, was worse at those times, and the patient was troubled with frequent and painful micturition. No special condition of the pelvic organs has been found in these cases, but thickened and dilated tubes, anteflexed and retroflexed uteri, conical cervix with pinhole os, chronic endometritis with lesions of the os, ovarian tumors, and ovarian thickening—all have been found in different cases. In the present case, examination showed the external genitals and vagina normal, but there was considerable leucorrhœa. The cervix felt large and indurated, and mushroom-like in shape, with enlarged Nabothian follicles, most marked on the posterior lip. On both lips was a lage area with a "velvety feel." The cervix was transversely fissured, and the posterior lip felt hard and shotty. The fornices were free; the uterus was normal in size and freely movable, and lay rather more to the right side than normal. As seen by the speculum, the discharge issued from the external os, and was white and glairy. The cervix was large and much fissured, both lips were everted, and showed large patches of granular erosions, and several follicles the size of sago grains. Treatment of the local conditions was followed by relief of the intermenstrual pain for the first time in five years.

Phlyctenular Conjunctivitis.—In the treatment of this condition, Kenneth Scott lays stress upon the necessity of improving the condition of the system by body cleanliness when necessary, by the adoption of warm but light clothing, extra nourishment, food being administered in small and frequent portions, and malt preparations. In regard to local treatment, he believes that every endeavor should be made to assuage the local inflammation. Complete rest of the eye is secured by atropine. In the milder cases, further rest and protection are afforded by the application of a dry cotton-wool pad with a bandage, and if a single thickness of muslin smeared with vaseline is placed next the skin, the secretions do not gather and dry on the eyelashes; thus agglutination of the margins of the eyelids is avoided, and also the harmful retention of secretions within the conjunctival sac. In more severe cases, additional measures are employed. Hot fomentations, changed at frequent intervals, are applied during one hour, either once or twice in the day. The solution which is found most useful for this purpose is salicylic acid in water, 1 in 200, to which are added, in the form of tincture, small proportions of aconite (two parts), arnica (four parts), belladonna (eight parts), and opium (ten parts). Sometimes the last of the fomentations is allowed to cool on the eye, and remain until the next time for repeating it is due, which may be either on that day or the following; at other times it is replaced during the interval with a warm pad of dry cotton-wool. In those cases in which the phlyctenula is situated on the surface of the cornea, there is often very great photophobia, but relief is speedily obtained by instilling some cocaine along with the atropine; and, by holding the eyelids apart for some seconds, the solution has time to take effect before it is washed away by the flow of tears. When there is marked blepharospasm, and more especially when an excoriated fissure has formed on the skin at the outer commissure of the eyelids, relief is afforded by simply dividing the outer canthus. This canthectomy is readily done by the use of a strong pair of blunt-pointed angular scissors.

Journal of Experimental Medicine, October, 1901.

Observations on a Case of Cyclic Albuminuria.—The patient of L. B. Mendel and D. B. Hooker was a young man apparently healthy, who was a laboratory student. Variations in diet did not seem to produce any concomitant variations in the proteid excreted. This point was tested during periods of feeding with a preponderance of carbohydrate and proteid food and again during periods of fasting. It was found that when the patient remained in bed, and perhaps during the period immediately after rising, the urine was usually free from coagulable proteid. The excretion then began gradually increased in quantity until about noon, when it fell off again; a second but smaller rise occurred later in the afternoon, and toward evening the output was again greatly diminished. The effect of muscular exertion, as noted in long walks, did not seem to vary the amount of proteid excretion, nor did posture act as an excitant to the abnormality noted. The most conspicuous proteid in the urine was albumin. Globulin was not found. Nucleo-albumin and proteoses were likewise absent.

Some Experimental Data on the Significance of Concentration and of Multiplicity of Area in Hypodermic Injections.—From experiments on rabbits, S. J. Meltzer concludes that in hypodermic injections the distribution of poison in several parts of the body is more effective than the injection of this quantity in a single dose into one place. The experimental substance used was strychnine. Other experiments demonstrated that the bulk is nothing and the concentration everything; the doses being equal, the more concentrated the injected poison is, the stronger is the result. The meaning is plain: the osmotic pressure is the most important factor in the process of absorption. The general conclusion therefore is that the effect of the subcutaneous injection depends to a considerable degree upon the concentration of the injected solutions, and is materially influenced by a greater distribution of the injected quantity over several areas.

Alloxuric Excretion in a Case of Leucopenia.—The patient in the case reported by R. Hutchinson and J. J. R. Macleod was a woman of thirty-seven years. She suffered from Malta fever, presented an enormously enlarged spleen and a large liver, but no glandular enlargement. She was confined to bed, and was kept on a diet consisting of eggs, milk, bread, and farinaceous foods, but containing no flesh nor other purin-yielding ingredients. The exact amount of food consumed was ascertained, and the urine was collected each day. The fæces were neglected, since no appreciable amount of purins is lost with them. An elaborate series of examinations of the urine was made and the conclusions are thus stated by the authors: 1. In the case investigated, one of Malta fever, the leucocytes were reduced to between 1,500 and 3,000 per cubic millimeter. 2. Notwithstanding this, the alloxur bodies and the phosphoric acid in the urine, the patient being on an alloxur-free diet, showed no distinct diminution from the normal. 3. The suggestion is made that this result may be due to the leucopenia being brought about by an increased destruction of leucocytes in the spleen rather than to a diminished activity of the bone-marrow.

Society Reports.

NEW YORK STATE MEDICAL ASSOCIATION

Eighteenth Annual Meeting, Held in [illegible] October 21-24, 1901

JOHN A. WYETH, M.D., of New York, PRESIDENT

First Day—Monday, October 21

THE meeting of the Council and Fellows, the governing body of the association, was held in the afternoon. The session was wholly occupied with executive business.

Officers Elected.—Dr. Alvin A. Hubbell, Buffalo, *President;* Dr. W. H. Biggam, Brooklyn, *Vice-President;* Dr. Guy D. Lombard, New York, *Secretary;* Dr. E. H. Squibb, Brooklyn, *Treasurer;* Dr. Irving S. Haynes, New York, *Chairman of the Committee on Arrangements;* Dr. E. E. Eliot Harris, New York, *Chairman of Committee on Legislation;* Dr. J. W. S. Gouley, *Chairman of Committee on Literature;* Dr. Alexander Lambert, *Chairman of Committee on Public Health and Medical Charities;* Dr. J. Riddle Goffe, *Chairman of Committee on Publication;* Dr. C. E. Quimby, New York, *Chairman of Committee on Nominations.*

Second Day—Tuesday, October 22

The Correction of Deformities Following Osteitis of the Knee.—Dr. Wisner R. Townsend, New York, read this paper. He said that it was generally agreed that all except very slight deformity should not occur under proper treatment unless the necessary co-operation of the patient was lacking. The application of force under anæsthesia would correct most cases. Statistics showed that under the protective plan of treatment 95 per cent were cured with motion of the joint. Cutting the hamstring tendons might not be demanded. If the external tendon required cutting, this should be done through an open incision to avoid injury to the popliteal nerve. Excision was rarely indicated, because osteotomy is less dangerous, is not so liable to cause relapse, and does not sacrifice so much time. The interference with growth after excision had led most surgeons to abandon this operation in children. Cuneiform osteotomy was only indicated when the deformity is extreme.

Appendiceal Fistula.—Dr. John B. Deaver of Philadelphia, Pa., presented this paper. He said that this was a preventable sequel to operations for appendicitis, for it would be practically unknown if operation were uniformly undertaken in an early stage. The least dangerous fistulæ were those in which an abscess ruptures into the cæcum, colon, or rectum, as in this variety the danger of intestinal obstruction is minimized and the exit for the pus is a safe one. However, he had known even these cases to terminate fatally. In many cases in which the appendix was left behind, it acted as a foreign body and kept open the fistula. In these cases the discharge might be almost pure mucus—indeed, such a discharge indicated almost certainly the presence of the appendix and its connection with the fistulous tract. Fecal fistulæ of the large bowel were more apt to heal spontaneously than fistulæ connected with the small bowel. If the appendiceal fistula were non-fecal, a careful search should be made for a foreign body, care being taken not to convert such fistula into a fecal one by wounding the bowel. When a fistula developed, the drainage should be removed and the tract should not be washed out any longer. In the experience of the author, fistulæ of the small bowel usually require a section. He preferred to do an end-to-end anastomosis without mechanical appliances, using instead of them sutures. Fistulæ of the large bowel are to be resected or repaired according to the judgment of the operator in the individual case. The surgeon should especially guard against overlooking the presence of more than one fistula.

Dr. De Lancey Rochester of Buffalo said that he had formerly favored temporizing and using the morphine treatment in the beginning with the object of doing an operation in the interval, but further experience had convinced him that it was better to resort to operation promptly whenever consent could be obtained.

Dr. Frederick Holme Wiggen of New York declared that the important thing in every case, even in suppurative ones, was to go in and remove all the diseased tissue. If this were done, there would be no danger of fistula and no necessity for drainage. He was glad to hear the author state that the fistula should not be washed out, for he had frequently known such fistulæ to be kept open for a long time by physicians who should have known better, persisting in irrigations. The same treatment recommended by Dr. Deaver would usually succeed, but occasionally, where the bowel had become flexed and adherent, the intestinal contents would be forced through the fistulous opening, and in order to cure such a fistula it was necessary first to remove the obstruction of the bowel. He did not agree with the reader of the paper that the cæcum must always be removed. The important point to remember was the necessity of removing all diseased structures.

Dr. E. D. Ferguson of Troy reported several cases to show some of the difficulties sometimes encountered. Prompt operation should be the rule, and it should be most thoroughly done, but occasionally, even under these conditions, a fistula would develop.

Dr. Gibbon of Scranton, Pa., declared that, in his opinion, the time to operate for appendicitis was before the inflammation had begun.

Dr. S. Bussby Allen of New York said that he was under the impression that about as many persons recover under the medical as under the surgical treatment of appendicitis.

Dr. Parker Syms of New York said that while it was quite possible that 80 per cent. recover from individual attacks of appendicitis, this did not mean the survival of 80 per cent of those having appendicitis, which is a chronic affection. Even if 80 per cent. did survive without operation, a mortality of 20 per cent. was certainly dreadful, when it was recalled that there should be almost no mortality from cases operated upon early. There was a period in every case of fatal appendicitis when the patient could have been saved by prompt and proper surgical care. In his experience, it had been the attending physician, and not the patient, who had been averse to operation.

Dr. J. R. Sturtevant of Theresa said that, although a country doctor, he was becoming more and more convinced of the advantages of the surgical treatment of appendicitis.

Dr. Allan A. Jones of Buffalo said that he was prepared to-day to tell all his patients that when the diagnosis of appendicitis had been made, an operation should be done immediately or in the interval.

Dr. John Edwards of Gloversville said that he had successfully treated many cases of appendicitis by using small doses of calomel throughout the attack and avoiding the use of morphine.

Dr. C. B. Teefts of Utica said that in accordance with the sound teaching that the physician should found his treatment upon an effort to remove the cause, he could not see how there could be any basis for the medical treatment of appendicitis. He knew of no drug which would remove the appendix. Moreover, he had followed up some cases of alleged cures of appendicitis by medical means, and had invariably found these persons far from cured.

Dr. Watt of Syracuse said that appendiceal fistula could be almost surely prevented by timely operation. Our duty was to adopt that method of treatment by which the greatest number could be saved in proportion to the number affected; it was, therefore, the duty of both the physician and surgeon to advise prompt operation in appendicitis.

Dr. Alfred T. Livingston of Jamestown spoke most

earnestly against the too common plan of giving purgatives. Such practice was both irrational and mischievous, because it interfered with nature's efforts at cure.

Dr. DEAVER closed the discussion. He said that he did not wait for well-marked symptoms of appendicitis, but operated as soon as there was appendiceal colic, pain, rigidity, and tenderness. The laity seemed to him to be better informed than the medical profession at large concerning the modern and best treatment of appendicitis. This was well shown by a question that had once been put to him by a society lady, viz.: "Why don't you surgeons take out the appendix when you tie the navel cord?" He knew of a man who had been "cured" of appendicitis forty-eight times and had been operated upon in his forty-ninth attack.

The Electrophone as an Aid to Deafness.—Dr. SAMUEL G. TRACY of New York demonstrated the action of this instrument, which he had invented. It is an electrical device, combining the principles of the microphone and telephone, and is so constructed as to magnify sound at least five times. It is intended to supersede ear trumpets and conversation tubes. The essential parts are a sound transmitter, a sound receiver, a specially constructed induction coil, and an electric battery. The battery is a dry cell, which does not require renewal oftener than about once a month. The instrument could be used as an aid to hearing in about 80 per cent. of cases of chronic catarrhal deafness and in a small percentage of cases of deafness arising from other causes. It also possesses some therapeutic value from the fact that it gives activity to a dormant auditory apparatus. It should also prove useful as an aid in the instruction of deaf mutes.

Malignant Growths.—A symposium on this subject was presented, and was participated in by the following:

The Clinical Course of Cancers with Reference to Their Resemblance to Inflammatory and Infectious Processes.—Dr. ALBERT E. WOEHNERT of Buffalo opened the discussion with this paper. He said that environment plays some part in the production of cancer. Like tuberculosis, it has no period of incubation. Metastases may occur early and be widely distributed. According to Osler, ulceration and metastasis do not constantly affect the temperature. The more rapid the growth, the greater the leucocytosis. It was reasonably clear that cancer had its own toxæmia, and that the latter might cause a fatal termination without regard to the local process. Sometimes it produces a coma similar to that observed in diabetes. In a general way, it might be said that the more rapid the growth and the metastasis the greater the toxæmia.

The Present Status of the Infectious Theory of Malignant Neoplasms.—Dr. GEORGE BLUMER of Albany considered this subject. He said that the frequency of cancer of the uterus would lead one to suppose that if cancer were communicable, cancer of the penis would be quite frequent; as a matter of fact, it was so comparatively rare as to refute this theory. The so-called cancer parasite is usually intracellular. It gradually grows larger and often develops radial striæ. The nucleus of the cancer cell is usually plainly visible and is pushed aside by the parasite. The author then critically reviewed the experiments in this field, and came to the conclusion that no one had, up to the present time, been able to cultivate successfully an organism or a group of organisms from malignant growths. It had been claimed that, as a result of inoculation experiments, tumors had been produced; but these, the speaker asserted, had been proved to be only granulomata. Certain facts regarding the distribution of malignant neoplasms were suggestive of their infectious origin, but much more extensive investigation was necessary before any definite conclusions could be reached.

Intrathoracic Growths.—Dr. ALEXANDER LAMBERT of New York treated this topic. He said that in the majority of cases the diagnosis [illegible] could be made if there were some one symptom present to arouse suspicion of the presence of such a tumor. Paroxysmal breathing and cough are almost always present. The peculiar spasmodic dry cough should always direct attention to the mediastinum. Intrathoracic growths are very apt to cause a local bulging and alteration in the shape of the chest; should be carefully sought for.

The Estimation of the Malignancy of Tumors with Reference to the Reported Cures of the Disease.—Dr. JAMES EWING of New York carefully considered in this paper the different varieties of malignant disease, and by a description of each showed clearly that our knowledge of the prognosis must remain very imperfect until surgeons learn sharply to differentiate the varieties, and report their cases in accordance with such classification.

The Treatment of Carcinomatous Growths by Caustics.—Dr. ANDREW R. ROBINSON of New York took up this phase of the subject, confining his remarks, however, to cutaneous epitheliomata. He said that caustics had long been in use for the treatment of this disease, notably nitrate of silver, chloride of zinc, caustic potash, and the acid nitrate of mercury. Chloride of zinc destroys much normal tissue, and hence possesses no advantages over the knife. Caustic potash penetrates, and the slough which it produces is permeable. Arsenious acid seems to have a special destructive action on pathologic epithelia. Not one in twenty cases of epithelioma of the face could be as well treated by the knife as by the proper use of caustics. Arsenious acid was not only a caustic, but an agent which is selective in its action. It was particularly useful in cases of cancer of the face. Recurrence was much less common than by simple excision.

Malignant Disease of the Nose and Accessory Cavities.—Dr. JOSEPH S. GIBB of Philadelphia, Pa., discussed this subject. Speaking of sarcoma of the nares, the author said that pain is absent in the majority of cases. Unilateral destruction of the nares was early noted by the patient. There was a preponderance of these cases among males. No period of life was exempt. By far the larger number of these sarcomata are of the round or spindle-cell variety. The prognosis was unfavorable, return to health being quite uncommon. Carcinoma of the nose, unlike sarcoma, spreads rapidly into the sinuses, involving both the soft and hard tissues. The pain was the most characteristic symptom, and was present very early. Increasing experience tended to make one disinclined to interfere surgically with carcinoma of the nose. Unless the disease were completely removed, the operation would only serve to aggravate the condition. Carcinoma of the accessory sinuses is very rare.

Cancer of the Large Intestine.—Dr. JAMES P. TUTTLE of New York read this paper. Carcinoma, he said, was especially prone to develop in the rectum. Thus, in a series of over 20,000 cases of malignant disease it had been found that the large intestine was involved in 1,220 cases, and that of this number about 506 were in the large bowel above the rectum. Next to the rectum, the cæcum is the most frequent site. Malignant disease of the large intestine occurs most rarely in the transverse colon. It was now known that when cancer occurs in persons comparatively young, it is in those individuals whose tissues are prematurely old. There were three principal methods of treatment, viz.: (1) excision, (2) enterostomy, and (3) enteroanastomosis, or the side-tracking of the fecal current. After excision, life is usually prolonged two years; after enterostomy, nine or ten months, and after enteroanastomosis, seven or eight months. The immediate mortality was higher after enterostomy, because it is not the operation of choice, but is done as an urgency measure. The third method gives the lowest immediate mortality,

about the same proportion of life, and the patient is much more comfortable.

Malignant Disease of the Penis.—Dr. HENRY H. MORTON of Brooklyn spoke on this topic. He said that malignant disease here is almost invariably epithelial carcinoma. It usually begins on the prepuce or glans as a warty excrescence. The existence in this situation of a sore of long standing, with a hard base in a person of advanced years, points to epithelioma of the penis. The technique of amputation of the penis was then described with the aid of diagrams.

Dr. S. SHERWELL of Brooklyn opened the general discussion with some remarks on Dr. Robinson's paper. He, too, favored the use of the acid nitrate of mercury, which he applied after curetting and thorough cocainization. The application is left for fifteen or twenty minutes, and is then neutralized with bicarbonate of sodium.

Dr. ALLEN A. JONES of Buffalo reported an advanced case of supposed malignant disease which was remarkable because of the existence of only a mild anæmia and a leucocytosis of the polymorphous variety.

Dr. STEPHEN SMITH of New York detailed an experience he had had at one time in the treatment of cancer by the application of anhydrous sulphate of zinc. This, when dusted on the surface, produces a light slough, and leaves a healthy granulating surface. The treatment was only slightly painful, and, in his hands, had acted far better than arsenious acid.

Dr. J. A. BODINE of New York said that as arsenic would not destroy the normal tissues when applied for from six to nine hours, this agent was of diagnostic as well as therapeutic value. The excellent results obtained with this agent were attributable to the secondary inflammatory area, and for this reason he now used the actual cautery instead of the V-shaped incision for the removal of epithelioma of the lip. The caustic which he prefers is composed of arsenious acid, two parts; gum arabic and orthoform, of each one part. The physician should remain with the patient the whole time the paste is on, and the latter should be removed hourly to note its effect. The treatment was not wholly without danger. For the removal of the slough, the speaker recommended digestion with papoid.

The Daily Medical Inspection of Schools.—Dr. FREDERICK W. LOUGHRAN of New York read this paper. He said that such inspection tended to check disease, both acute and subacute, and diminished the total number of days absent. He described in detail the method of inspection adopted in New York City.

Dr. JAMES LEE of New York said that he would go further than the author, and would urge that the inspection extend beyond the domain of contagious diseases, and take cognizance of neurotic states and affections of the eye and ear, as well as of the sanitary condition of the school buildings. The attention of the medical profession was directed to the vast amount of home work required of school children, and the resulting ruin to the health of many, especially of young girls near the age of puberty.

Ethyl Bromide and Ethyl Chloride Respectively as Surgical Anæsthetics. Dr. S. ORMOND GOLDAN of New York read this paper, and exhibited an apparatus which he had devised for the scientific administration of these agents. The author said that both of these agents had been considered to be safer than chloroform because of their lower boiling point, but as a matter of fact the lower boiling point causes more rapid action, and while it can be more easily exhaled, it can also be more easily inhaled, and in this lies the danger. For very brief operations these agents were probably better than chloroform or ether, but not superior to nitrous oxide. Ethyl bromide is safer than ethyl chloride, because it is not required in the same concentration. A condition of analgesia with consciousness was often observed when ethyl chloride or ethyl bromide is used. The use of these agents prior to chloroform was quite unnecessary, and somewhat dangerous. These agents should always be administered with the patient in the recumbent position.

Dr. JAMES P. TUTTLE of New York said that after his experience with ethyl chloride in 220 cases, he could not agree with the author as to the danger of this agent. Ethyl chloride had been used in New York City 2,000 times for anæsthesia without a single death, and, so far as he knew, without serious symptoms. For administering it, there was nothing better than the old chloroform inhaler. For operations lasting from five to ten minutes, it was perfectly safe, but the muscles are not so completely relaxed as with ether. It frequently causes nausea, but this is quite transient and is not associated with headache. This anæsthetic was particularly useful in alcoholic subjects, and for short operations was far more convenient than nitrous oxide.

Perforation of Gastric Ulcer, with Report of a Case Successfully Operated upon Sixty Hours After Perforation.—Dr. LUCIUS W. HOTCHKISS of New York presented the report of this interesting case, and described briefly the symptomatology and treatment.

The Therapeutic Value of Alcohol as Understood at the Beginning of the Twentieth Century.—Dr. FRANK WELLINGTON DENNIS of Unionville read this paper. He pointed out that five and a half times as much money was spent on alcohol as on education. The author gave a rapid review of the action of alcohol, and gave extracts from a mass of carefully collated statistics. Particularly striking were the statistics quoted from the experience of life-insurance companies. Thus, one actuary points out that a total abstainer at the age of twenty has an expectation of life ten years greater than those who use alcohol. Alcohol should, therefore, be prescribed by the physician for disease only when fully alive to the responsibility he assumes.

Pelvic Inflammation in the Female; Its Diagnosis and Management by the General Practitioner.—Dr. ABRAM BROTHERS of New York was the author of this paper. He stated that all exudates in the pelvis lasting for months or years contain a pus nucleus. Traumatism plus infection would usually be found to be the starting point of pelvic inflammation. The presence of pus constitutes a sharp line between the medical and surgical treatment. Owing to lack of time, the full paper was not read.

Skin Diseases of Special Interest.—Dr. GROVER W. WENDE of Buffalo presented this topic through the medium of lantern slides.

Third Day—Wednesday, October 23.

Arteriosclerosis.—A symposium on arteriosclerosis was presented under the following headings:

Arteriosclerosis: Importance, Definition, Etiology, and Symptomatology.—Dr. Charles E. Nammack, New York, opened the discussion with this paper (see page 649).

Cardiac Manifestations of Arteriosclerosis.—Dr. DE LANCEY ROCHESTER of Buffalo read this paper. The chief cardiac manifestations observed clinically are hypertrophy, with or without dilatation and degeneration of the myocardium, certain valvular lesions, and angina pectoris. The general management of the underlying arteriosclerosis constitutes almost the whole treatment. It was questionable whether digitalis had any place in these disorders, because of its dangerous action on the heart and arterioles. The fluid extract of cactus accomplished all that digitalis would and without its dangers, and when combined with the fluid extract of valerian would be found exceedingly valuable where the nervous symptoms were prominent. The inhalation of amyl nitrite and the hypodermic use of nitroglycerin, sometimes with the addition of morphine and atropine, and the use of a hot foot-bath, constituted the additional measures

likely to be required in the treatment of the attacks of cardiac disorder.

Management and Therapeutics of Arteriosclerosis.—Dr. Egbert Le Fevre of New York discussed this topic. He said that arteriosclerosis does not affect all of the arterial tract uniformly. The work thrown on the heart could be relieved by the use of nitrite of amyl, nitrite of sodium, nitroglycerin, and others of this class. Their action, however, is very transient, varying in duration, according to the one selected, from twenty minutes to two hours. He cautioned against their free use, believing that the giving of large doses at comparatively short intervals is a bad practice and tended to hasten the degeneration. They were, however, very useful in emergencies. Abundant clinical experience had shown that the iodides have the power of lowering the blood pressure without diminishing the force of the cardiac systole. In addition to this, he had learned from experiments that the circulation is not so easily disturbed by reflex action during the administration of the iodides. He believed they control the muscular spasm of the heart and arterioles. As the potash salt was the most depressing, it was not used if cardiac insufficiency existed; but it was of service when there was cardiac hypertrophy. The syrup of hydriodic acid could be given in drachm doses and gradually increased to four drachms, three times a day. The development of symptoms of iodism should be avoided. Cardiac hypertrophy in this disease was not a pathological result, but was dependent upon the effort of nature to relieve the diseased state of the arteries. Occasionally, nature was prodigal in this effort and the hypertrophy would become excessive. It then became the duty of the physician to diminish this by giving aconite in doses of ten minims, every six hours, or by the use of spartein sulphate in doses of one-fourth to one-half grain. The latter acts here as a cardiac sedative and not as a stimulant. Sooner or later the cardiac hypertrophy would fail to keep pace with the progressive obstruction in the arteries, and the nutrition would then suffer. This called for the use of two to four minims of the tincture of digitalis, or half a grain of the English leaves, at bedtime.

Dr. C. E. Burnby of New York said he now looked upon all fibrotic processes as pathetic and not pathic.

Dr. Sturtevant said that the preparations of cactus grandiflora vary so greatly that the dose varied from one or two to fifteen minims.

Dr. James J. Walsh of New York said that many cases of apparent neurasthenia were dependent on arteriosclerosis. Heredity was an important factor in the etiology, and our treatment must be prophylactic. It was just here that the family physician could do so much by wisely advising predisposed persons concerning the most suitable occupations and modes of life.

Dr. Charles G. Stockton of Buffalo said that one of the cases reported by Dr. Rochester, in which there had been intense epigastric pain, reminded him of the fact that gastralgia was often present in these cases, and took precedence, by reason of its prominence over the cardiac condition.

Dr. Frank W. Higgins of Cortland asked for the experience of others in the treatment of arteriosclerosis by the corrosive chloride of mercury and by arsenic and gold.

Dr. Allen A. Jones of Buffalo thought considerable importance should be attached to continued nerve irritation and strain as a causal factor. Those who are hereditarily predisposed to this affection often exhibit a nervous spasm of the arterioles. In this connection it should be remembered that coffee irritates the arterioles, causes their contraction, lessens the cardiac force, and throws the blood back into the larger arteries.

Dr. C. E. Nammack of New York said that in the terminal stage, in which there was cardiac dilatation, associated perhaps with general dropsy, digitalis would be found of signal benefit. He usually gave it in the form of the first infusion of the leaves, or else in combination with calomel and squill, and followed this with sulphate of magnesia. The "strenuous life" of the present day was certainly responsible for a good deal of arteriosclerosis. The diagnosis of neurasthenia should not be applied to those cases in which there is accentuation of the second sound of the heart and an increase in the cardiac impulse. He had used the bichloride of mercury, but did not consider it equal to calomel.

Dr. Rochester said that he would still maintain that there was very little use for digitalis in cases of arteriosclerosis with accompanying disease of the heart, because it threw a greater strain on the heart. While digitalis might be useful as a very temporary measure, where the heart had become dilated, it was, in general, contraindicated. It was, in his opinion, a pernicious practice to give continuously small doses at night; far better than giving the patient this false sense of strength was the practice of keeping the patient at rest in bed. He had found only one useful preparation of the fluid extract of cactus. It does not produce the harmful effects of digitalis, but nevertheless should not be used continuously. When the heart had become dilated, strychnine should be given. He had obtained entirely negative results from the gold preparations.

Dr. Le Fevre, in closing, said that he had found bichloride of mercury only useful as a means of relieving the heart by increasing the activity of the kidneys. The gold preparations had not given him good results. He did not believe strychnine had any direct effect on the heart muscle, or on any other; it was only through its action on the nervous system that the muscles are stimulated.

Blood Examination from the Standpoint of the General Practitioner.—Dr. Frank W. W. Higgins of Cortland contributed this very practical paper. After considering some of the minor details that should be observed in general practice, in order to make such work possible, the author took up several special topics. He said that it was a useful thing to determine the specific gravity of the blood. A convenient and accurate method of doing this consisted in mixing chloroform and benzine in such proportions that the drop of blood neither rises nor sinks, and then using a urinometer or suitably graduated hydrometer. He had found the specific gravity of the blood vary from 1037 to 1067, and in cases of dropsy and leukæmia to correspond quite closely with the percentage of hæmoglobin. The estimation of the blood corpuscles is made quickly and with fair accuracy by the aid of the centrifuge. A margin of error of at least 5 per cent. must be allowed in the determination of the hæmoglobin, because of individual differences in using the color scales. A good general rule in practice was not to undertake a surgical operation if the hæmoglobin percentage is as low as thirty. A great increase in the number of leucocytes means leukæmia. A leucocyte count of 12,000 to 50,000 means an infection, most often with the formation of pus. Leucocytosis, while often of the highest diagnostic value, should never be considered pathognomonic. It was especially useful in distinguishing appendicitis from typhoid, and in detecting pneumonia when the physical signs are masked. A diminished leucocytosis might be as valuable as the Widal reaction in the differential diagnosis of typhoid fever. The leucocytosis caused by anæsthesia was so transient that it was not apt to cause confusion. The leucocyte count *falls* in suppurative cases when the abscess *is walled off*. A diminution of the red corpuscles constitutes the only rational basis for the use of iron and arsenic. The study of the stained specimen of blood was the most interesting of all the steps in the examination of the blood, and yet it was just here that the novice found that the textbooks failed him. Cabot strongly recommends the use of the tri-acid stain, but in order to insure success it was essential that the specimen be thoroughly heated until it assumes a

golden-yellow color. The existence of an eosinophilia might enable the physician to detect a trichinosis which had been mistaken for rheumatism.

Dr. Richard C. Cabot of Boston, Mass., said that he was a general practitioner, and as all his blood studies had been carried on while acting in this capacity, it was perfectly feasible for others to do the same. It was now possible by the use of the hæmoglobinometer, devised by Tallqvist, a Finn, to determine within a few seconds the hæmoglobin, and with an error of only 10 per cent. This devise consists of a pad of filter paper and a color scale. On this paper the drop of blood is placed, and then its color is compared with those found on the scale of colors. The ease with which this instrument could be used, and its slight cost, $1.25, make it peculiarly suitable to the needs of the general practitioner. He did not attach much value to the specific gravity determination, because it practically gives no information not obtained by determining the percentage of hæmoglobin. While leucocytosis might mean the presence of pus, it might only be indicative of toxæmia, and the tetter might be the result of purulent inflammation, of uræmia, and various other conditions.

Conservative Surgery for Tuberculosis of the Lymphatic Glands of the Neck.—Dr Parker Syms of New York said that tuberculous glands might undergo: (1) Cheesy degeneration; (2) Fibroid degeneration; (3) Atrophy and absorption; (4) Abscess formation; (5) Calcification. Some surgeons recommend complete removal of the chain of glands involved, together with the fascia and fat; but his objections to this radical operation were: (1) It is not necessary in the vast majority of cases; (2) It does not avoid deforming scars; (3) It is not a sure and permanent cure; (4) It increases rather than diminishes the danger of systemic infection, and (5) It is a severe tax on the patient's endurance. It was, however an operation which was applicable to neglected cases in which many or most of the glands are in an advanced state of degeneration, and to those cases in which the progress of the disease is persistent and more conservative methods fail. In addition to the use of well-recognized hygienic measures, the author recommended certain local treatment. Thus, if the enlarged glands were apparently not broken down, the skin over them should be anointed with a 10-per-cent. ichthyol ointment. If one or two glands remained persistently larger than the rest, it might be well to remove such glands through a small incision. Broken-down glands should be opened before rupture, and a drain of gauze or rubber tissue used for a few days. They should then be treated with a 10-per-cent emulsion of iodoform and glycerin. Progress would be slow, but the final result would ordinarily be very satisfactory.

President's Address.—Comments on Some New Surgical Methods.—Dr John Allan Wyeth of New York delivered an address on the above theme. He first took up medullary narcosis, or intraspinal cocainization, and held that it was manifestly unfair not to give full credit for the discovery of this method to Dr. August Bier. The published observations of our countryman, Dr. J. Leonard Corning, had not really covered the same field. The speaker said that he would not hesitate to employ it in persons who had a strong prejudice against the usual general anæsthetics. The technique recommended was that already described by Dr. W. R. Stone of New York. Cocainization and a small incision should precede the introduction of the needle, and it was well to allow a quantity of cerebrospinal fluid to escape equal to that to be injected.

Obliteration of Bloodvessels by Injection. The speaker said that Dr. R. H. M. Dawbarn's method of starving inoperable neoplasms by ligation of the main artery supplying them had suggested to him that something might be accomplished by injecting some fluid which would cause an obliterating endarteritis. In January, 1901, he had undertaken experiments of this kind on dogs. Boiling water had been injected into the external carotid and it had been found that it was possible in this way to obliterate an artery down to its terminal branches. An encouraging result by this method of treatment on the human subject was reported.

Prostatectomy.—The various methods of performing prostatectomy were detailed, and the statement made that the mortality of this operation had fallen steadily, keeping pace with improvements in technique. Dr. Wyeth said he looked upon this operation as one of the most valuable contributions to surgery made in the last decade.

Removal of the Ovaries in Cases of Cancer of the Breast.—This interesting topic was briefly touched upon, and the statement made that the results had been sufficiently encouraging to justify the continuance of these experiments.

Value of Bacteriological and Pathological Research in Diagnosis, Prognosis, and Treatment in Practical Surgery.—This was the special subject for discussion considered in the three following papers:

Iodophilia.—Dr. Richard C. Cabot of Boston, Mass., discussed this topic. He said that iodophilia was simply the reaction of the polynuclear leucocytes to iodine. The solution employed is composed of iodine, one part; iodide of potassium, three parts; water, one hundred parts, with sufficient gum arabic to make a thick syrup. This solution will keep for several months. The red cells of normal blood are stained by this solution a bright yellow, and the leucocytes are also stained yellow. If the reaction is positive, there will be a brownish color. The reaction is of two kinds, *i.e.* intracellular and extracellular, but the former is chiefly significant. The reaction is never observed in the nuclei, and is only found in the polynuclear leucocytes. The reaction is now known not to be due to glycogen, but we are still ignorant of the substance causing it. A person whose blood gives the iodophilia reaction was certainly sick, but the causes were various. This reaction had helped him greatly in a number of cases of appendicitis. In several cases in which the symptoms had been quite marked, but iodophilia had been absent, operation had shown only a comparatively mild inflammatory process. On the other hand, in a number of cases of appendicitis in which iodophilia had been present the operation had revealed abscess or gangrene. Cases of typhoid show iodophilia, due probably to a general toxæmia. It was present in bad respiratory disorders, such as asthma, in inflammations of any kind, such as pneumonia, abscess, and gangrene; in bad anæmias, whether primary or secondary, and in toxæmia.

Laboratory Differential Diagnosis in Surgery.—Dr. Simon Flexner of Philadelphia, Pa., took up this subject. He pointed out the value of laboratory work in both medicine and surgery, and touched upon the Widal reaction, blood examinations for malarial parasites, leucocytosis, the coagulation-time of the blood, and urine examinations.

Modifications in the Methods of Operative Surgery Resulting from Laboratory Research.—Dr. Joseph D. Bryant of New York cited illustrative cases from the records of Bellevue Hospital thirty years ago, and contrasted them with those of to-day in similar cases. He said that in an experience of thirty years he had not seen as many cases of pyæmia as he had observed during the six months that he had served as house surgeon of Bellevue Hospital.

The Use of the Pneumatic Cabinet.—Dr. Charles E. Quimby of New York presented an exhaustive paper on this subject, based upon an experience of nine years with this mode of treating essentially all forms of cardiovascular disease. He described the pneumatic cabinet as one large

enough to contain one person, and having a bellows by means of which the air within the cabinet could be rarified or compressed as desired. Pneumatic differentiation is a term which implies a difference of atmospheric pressure upon the lung and the thoracic cavity and upon the cutaneous surface. The speaker contended, and seemed to prove by many clinical reports, that pneumatic differentiation lowers vascular tension, and increases blood-flow, thereby improving nutrition.

Gunshot Wounds of the Hip-Joint by Reduced-Caliber Projectiles.—Major LOUIS A LA GARDE of Washington, D. C., read this paper, dealing with wounds in general made by modern bullets. He exhibited specimens and skiagrams, and stated that the destructive effects of gunshot wounds depend upon the sectional area, the velocity of the projectile, and the resistance encountered on impact. At the present time he would rather treat a man shot with a reduced-caliber bullet in the hip or knee than one shot in the tibia or femur. In modern times the mortality from gunshot wounds of the knee had been reduced over 78 per cent. The essayist predicted that, in the future, gunshot wounds of the hip-joint would prove to have as humane an outcome as in cases in which other joints were so injured.

Asthma of Blood Origin, and Not Nerve or Reflex.—Dr. G. N. JACK of Depew, in this paper, unfolded his theory of the origin of asthma, and pointed out as the cardinal feature the inability of the blood to absorb or carry a sufficient quantity of oxygen.

Dr. GEORGE F. COTT of Buffalo, in discussing the paper, said that while medicines, directed to improving the condition of the blood, often temporarily relieve asthma, they do not permanently cure it. The reader of the paper had very properly ignored the theory of the spasmodic origin of asthma, for no one had ever demonstrated spasm of the bronchi, though its existence had often been asserted.

Acne.—Dr. EDMUND L. COCKS of New York said that only two cases of acne in children had been reported. About 75 per cent. of the cases occur before the age of eighteen. It frequently follows chlorosis, and, in general, may be said to be a disease occurring in persons of low vitality having impaired digestion and circulation. Acne rosacea is a disease of middle life, occurring at the time of life when acne vulgaris usually disappears. The prognosis in acne vulgaris was usually good if the instructions of the physician were carefully followed. Treatment should not be neglected because of the resulting disfigurement. The blood and urine should be examined, and the diet and habits of life carefully inquired into. Massage, cold sponging, and outdoor exercise were beneficial. The face should be protected from cold winds, especially when riding in an automobile. Pastry, candy, hot bread, fried meats, potatoes, and alcoholic drinks should be avoided. Rice may be eaten in lieu of potatoes. Arsenic should never be used in any stage of acute cutaneous disease. Rhubarb, cascara, and similar remedies were usually indicated. Locally, the comedones should be removed, the lesions curetted, and a soothing lotion applied. The parts should be sponged with hot water at bed time. The application of pure carbolic acid would often prevent suppuration. Massage should be used after each local treatment.

Dr. FRANK D. REESE, Cortland, said he thought acne could be easily cured by attention to the habits of life and the local use of the nail-brush with the tincture of green soap.

A New High-Tension Electrical Machine and Ozone Generator.—Dr. G. LENOX CURTIS of New York exhibited this instrument and demonstrated its action. One great advantage of the instrument was its portability. The treatment, conducted with the aid of this instrument, was most applicable to rheumatism, gout, spinal troubles, and dyspeptic and neurasthenic conditions. He had succeeded also in curing within six weeks several cases of lupus of great severity and long standing.

Books Received.

While the MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will be promptly made of their receipt under this heading, it must be with the distinct understanding that its necessities are such that it cannot be considered under obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending October 19, 1901:

	Cases.	Deaths.
Measles	56	6
Diphtheria and croup	210	25
Scarlet fever	101	6
Smallpox	4	1
Chickenpox	19	..
Tuberculosis	231	130
Typhoid fever	100	23
Cerebrospinal meningitis	..	2

On the Care and Treatment in Convalescence from Functional Nervous Disease.—F. Savary Pearce says that first of all such patients must be schooled or educated in self-control. Great care should be taken in the gradual restoration to former physical activity. Patients often feel so much better that they overdo themselves, and so nature has no opportunity to accumulate strength. The most desirable forms of exercise during the late, ultimate convalescence from neural maladies are in a general way those different from the exercise gotten by the patient in his usual routine of life; and here again the psychologic element must enter prominently as the reason for this betterment. Exercises, therefore, that keep the patient away from his usual line of thought, or prevent him from thinking about self, are to be enjoined. And if the patient can be kept off his limbs, it will be more advantageous for rest of the central nervous system, and thus recreate that reserve force which has become wanting in them. So that rowing, canoeing, horseback riding, will be much more valuable than golfing, tennis playing, or bowling. Frequently, peptonization of the large quantities of milk taken will be of great value in aiding hypernutrition. The skilled use of massage is also a measure which will help metabolism in the muscle itself, as well as by mechanically forcing on waste products and giving vigor to the circulation; for frequently, in these cases, the cardiovascular system is not doing the physiologic duty required.—*International Medical Magazine.*

Treatment of Abortion.—Peter Horrocks (*Medical Press* August 21, 1901), divides the treatment into: (*a*) Avoidable; (*b*) unavoidable; (*c*) incomplete.

Rest in bed and some form of opiate are the best treatment. If in doubt, operate and clear out the uterus.

When there is serious hemorrhage, or when os uteri is so large, or expulsive pains so great and frequent that miscarriage is inevitable, allow it to take place, and, if need be, assist it either by puncturing the membrane or clearing out the uterus digitally under an anæsthetic.

When incomplete, it is best to clear out the remainder. In some cases it is useful to pack the vagina with gauze. The bleeding is stopped or lessened, and uterine contractions are promoted, and later on it is much easier to deliver.

Vaginal injections of hot lotions are recommended by some, but they are not very trustworthy.

Dilators may have to be employed and ovum forceps and a curette; but it is better to mutilate the fœtus than to damage the mother.

Everything must be done aseptically, and, if need be, the uterine cavity must be swabbed out with tincture iodi or some other antiseptic.

Diagnosis of Renal Infarcts and Renal Colic.—Rudolph Schmidt (*Wiener klin. Wochensch.*, May 9 and 16, 1901) concludes: (1) In all cases of renal colic, it should be determined whether the origin is intrarenal, *i. e.* due to the kidney itself, or extrarenal, that is, dependent upon ureteral obstruction; (2) pain of intrarenal origin is usually localized to the region of the kidney. The pain of renal infarct is continuous, the kidney is sensitive to pressure, and there is a marked sediment and a high percentage of albumin in the urine; (3) extrarenal pain is more intermittent in character and extends along the course of the ureters, which are sensitive to pressure. Acute hydronephrosis may supervene; (4) renal colic of intrarenal origin may be caused by (*a*) portion of the blood vessel of the kidney (ren mobilis); (*b*) sudden congestion of malignant or vascular tumors; (*c*) acute exacerbation of chronic nephritis; (*d*) renal infarcts; (5) in cases of renal infarcts, lying on the sound side increases the pain; (6) the renal artery may be entirely occluded and yet no symptoms exist; (7) oliguria occurs particularly with bacterial infarction.

The Average American.—Henry Gannet in *Everybody's Magazine*, September, 1901, treats of the above subject and says: "The average American is a statistical octoroon. If the blood in the veins of all our people, white and black, were pooled, and redistributed, each person would have about seven parts white and one part negro blood. The white strain in him, moreover, is by no means purely American. White strains of foreign origin derived from Germany, Ireland, Scandinavia, Canada, Great Britain, and the countries of Southern Europe are collectively more powerful in his composition than is the native strain. Thus going back only one generation, we find him to be a composite, the creation of widely differing bloods and nationalities. The peoples of the earth, from the Congo, under the Equator, to the Cape of Europe, have contributed, either immediately or remotely, to his composition. But with it all we find the Anglo-Saxon strain the dominant one."

German Measles.—Kraatsch says that the swelling of the cervical lymphatic glands, especially those at the back of the neck and over the mastoid, is pathognomonic of German measles and distinguishes this disease from measles.

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended October 19, 1901:

		Cases.	Deaths.

CARBONATE OF CREOSOTE AS A REMEDY FOR PNEUMONIA, WITH A REPORT OF NINE CASES IN WHICH THE ADMINISTRATION OF IT HAS BEEN FOLLOWED BY REMARKABLY UNIFORM AND GOOD RESULTS.

By LEONARD WEBER, M.D.,

NEW YORK.

PROFESSOR OF MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL; VISITING PHYSICIAN TO POST-GRADUATE HOSPITAL; CONSULTING PHYSICIAN TO ST. MARK'S HOSPITAL.

A LITTLE more than a year ago, a very good paper on the treatment of pneumonia was read before the German Medical Congress by Professor Pel of Amsterdam. At the conclusion of it, he said that, inasmuch as his arguments were based on the observation of more than twelve hundred cases of pneumonia, they might be of some clinical value, but for the recommendation of any single method of treatment for pneumonia a successful series of many thousand cases would be required. Admitting the truth of this statement, I should not think of publishing a few cases of pneumonia in which good results had been obtained by giving creosotal, if they were the first which had been so treated; but there are a number of physicians here and abroad who say they have seen good results from it in a comparatively large number of cases, hence I feel no hesitation in giving the report of my own cases, because they are confirmative of those reported by others.

In a paper on the treatment of pneumonia read last winter before the New York Post-Graduate Clinical Society, and published in the *Post-Graduate Medical Journal* for June, 1901, I said that, while waiting for a reliable antipneumonic serum, which it is my belief will come soon, we can do no better than to treat and nurse the pneumonic patient through his illness according to well-established rules. A week after reading that paper, I came across an article by Dr. I. L. Van Zandt, published in the MEDICAL RECORD of March 30, 1901, under the title "A Résumé on Creosote in Pneumonia." There have been other observations on this subject in the medical journals of this country, but Van Zandt's is the only one I have read. The French have been the first, I believe, to employ creosotal in pneumonia and bronchopneumonia. Dr. Carsouté reports a series of successful cases before the Pædiatric Congress held in Marseilles in 1898; Dr. A. H. Smith, in the *New York Medical News*, 1899, mentions it; so does Dr. J. A. Gracy in the *Charlotte Medical Journal*, 1899; Dr. Charles E. Stokes, in the *Brooklyn Medical Journal*, in the same year, I believe, also recommended it in lobar pneumonia. Dr. J. W. Frieser, of Vienna, Dr. Meitner, *Medico-chir. Centralblatt*, June 22, 1900; Dr. M. Everson, *Aerztliche Centralblatt*, July 7, 1900, have also seen invariably good results following the administration of creosotal in pneumonia.

Upon the basis of all these positive reports, I now felt encouraged to try creosotal as a remedy for pneumonia, and I have done so in three private and six hospital cases which were under my care at the Post-Graduate Hospital during my service in April and May. In the care and treatment of the hospital cases, I have been most ably assisted by Dr. Adams of the house staff, who was untiring in the care and treatment of the cases, as well as in the keeping of correct clinical records of the same.

Cases of pneumonia in the wards of the Post-Graduate Hospital during April and May:

I.—Daniel M., aged forty-seven, mechanic, single, American. Had measles and scarlet fever in childhood; gonorrhœa and syphilis between eighteen and twenty-two. He is subject to colds and coughs during the winter months, and three days before his admission he had a severe chill at night, followed by pain in the left side of the chest, and a short, dry cough.

On admission, March 28, lobar pneumonia of the left side was fully developed; temperature 102.5°, pulse 112, respiration 40. Patient was restless and delirious at times, and continued that way until March 31, when treatment with carbonate of creosote was begun. Believing that it would be opportune to give the drug in gelatine capsules which could readily be taken, and would dissolve in passing along the intestinal tract, such capsules were put up after this formula:

℞ Carbonate of creosote . . . . . ½ oz.
Sapon. medicat. . . . . 1 dr

M. F. capsulæ No. 60. Two to be taken every three hours, ten to twelve daily.

April 1, patient has had 60 gr. of the carbonate of creosote. His temperature was 98.0°, pulse 96, respiration 22; he is quiet and coughs but little; consolidation of left lower lobe posteriorly and at the side from the fourth rib down; a few crepitant râles can be heard. Medication was continued, also 3 gr. of Dover's powder ordered to be given at 10 P.M., if the patient were restless; his bowels were kept moving by sufficient doses of sulphate of magnesia.

The creosote was continued at this rate until April 10, when he had taken one ounce of it. Temperature, pulse, and respiration had remained normal right along, his appetite and general condition were good; but, though the soft râles increased from day to day, resolution was not complete until April 14, when the patient was convalescent, put on a mild tonic, and discharged as cured April 22.

II.—Emily E., aged forty, widow, housewife, American, has had measles, scarlet fever, and typhoid fever, and rheumatism between her fifth and thirty-fifth year; badly nourished and anæmic-looking person. Three weeks before admission, she had an attack of catarrhal influenza, and two days before, sharp pain in left side, increasing sense of prostration.

Admitted March 27. She had much cough with thin mucous expectoration, some fever, which kep on increasing slightly until March 31, when the tem perature reached 101.5°, pulse 90, respiration 28, an a diagnosis of pneumonia of the left lower lobe pos

teriorly, and part of the upper lobe, could be readily made. April 1, creosotal treatment was begun and continued steadily until April 10, when 10 dr. of it had been administered. After the first twenty-four hours, the temperature never rose above 99°; respiration fell to 20; the pulse was weak, however, though regular, and indicated small doses of alcohol, which were ordered. During these ten days the area of consolidation had remained the same.

April 12, of the elixir of ferrum, quinine, and strychnine a teaspoonful was ordered four times a day. She was generously nourished, her bowels kept regular, and under rather free mucopurulent expectoration the pneumonia got well by lysis about the 20th, and the patient was discharged cured April 27.

III.—Jennie G., aged twenty-one, single, American, servant, had measles three years ago, which left a bronchial catarrh, making frequent exacerbations. A year ago, slight hæmoptysis occurred, not followed by fever or cough, and a week before admission she had pleuritic pain in the right side with some fever. When admitted April 17, she was found to have a pleuritic effusion in the right lower half of the thorax, existing probably for some time, but not interfering to any great extent with respiration and circulation; but there were also signs of congestion around a presumably old quiescent lesion in the right upper lobe; patient's temperature ranged from 100° to 102°; general condition fairly good. There being no immediate indication for aspirating the pleuritic fluid, we treated first the acute congestion in the right upper lobe by giving her creosotal at the rate of 50 gr. a day for one week, with the same result of reducing temperature to normal within two days; it remained so until May 1, when about six ounces of clear yellow serum were aspirated and the patient ordered to take solid food, very little fluid of any kind, to practise respiratory gymnastics by slow and forcible expirations through a short, hard rubber tube of $\frac{1}{16}$ of an inch bore, followed by deep and rushing inspirations. These special respiratory movements she was instructed to do a dozen times t. i. d. with the result that the compressed parts of lower lobes re-expanded rapidly, and marked general improvement followed. On May 11, respiration was almost as good and full on the right as on the left side. Right posterior apex showed slightly harsh expiratory murmur, indicating the old lesions mentioned above. Temperature, pulse, and respiration normal. Patient being somewhat anæmic, she was ordered to take Blaud's pills, and discharged cured May 15.

For many years I have been in the habit of ordering the above-described respiratory exercises for re-expanding the lungs after aspiration of pleuritic exudates; also in cases of bronchial catarrh with and without bronchiectasis, in fibrous and indurated processes of the lungs and the like, and have found this simple and handy procedure quite as efficient for the purpose as the use of more or less complicated apparatus.

IV.—Michael D., aged forty-seven, nurse, single, American; patient had gonorrhœa at eighteen, neither syphilis nor rheumatism. He used liquor moderately, worked rather steadily, and considered himself a healthy man up to two weeks before admission; at that time he was exposed for a period to cold and wet weather, and was taken ill rather suddenly with pain in the right side and back and high fever. Does not remember what occurred from that time until he was admitted May 2, with temperature 101°, pulse 128, respiration 22. The second mitral sound was found weak, the second pulmonary accentuated. The right lung consolidated posteriorly up to the crest of the scapula; a few dry crepitant rales here and there. There was slight icterus present, but the lower margin of the liver was not found to extend below the free border of the ribs. There was neither ascites nor anasarca; no vomiting. The patient was unusually quiet, almost apathetic. Temperature rose next day to 101.5°, but after two days' exhibition of carbonate of creosote at the rate of 60 gr. per diem it became normal.

May 4, pulse about 100, but weak. May 5, resolution began to set in, but the patient's general condition did not improve in measure. May 10, pulse much weaker, and strychnine, camphor, and caffeine were administered hypodermically; stimulants were also given. May 11, he had rallied somewhat and felt better, but on May 12 the heart failed to respond any further, pulse became imperceptible, and death ensued. The patient was certainly getting better of his pneumonia, but he succumbed to degenerative myocarditis, which we believed to be present after the very first examination of the patient. We were not allowed to make an autopsy.

V.—Camille M., aged thirty-four, actress, married, English; has never been pregnant, menstruation regular, but always painful and followed by a variety of neurasthenic symptoms; three months before admission oöphorectomy was performed upon her. On April 4 she had a chill, followed by fever and pain in the right half of thorax, and on admission April 6 we found pleuropneumonia of moderate extent on the right side with a temperature of 101° and pulse 89, respiration 24. Carbonate of creosote, as in the other cases, was administered, 50 to 60 gr. a day. Temperature fell to 99 after the first day of administration and never rose again. For the distressing cough heroin gr. $\frac{1}{12}$ had to be given two or three times a day, and cold compresses were applied on the right side to soothe the pleuritic pain.

April 10, all symptoms of pulmonary congestion had disappeared. April 12, she was put on mixtura ferri et ammon. acet. 2 dr. t. i. d. for tonic purposes and discharged in good condition April 15.

VI.—Arthur H. H., aged twenty-eight, single, English, salesman; was admitted March 16, when he either had or soon afterward developed pneumonia, concerning lower lobe of left side; he was treated symptomatically and remained in *statu quo*. April 1, hepatization was still well marked, fever present. The creosote treatment was begun April 2, and all general and local symptoms had changed for the better on April 3, and remained so until resolution was accomplished April 12; patient made a good and complete recovery and was discharged cured April 20.

Private Cases.—1.—Fred. W., aged twenty-four, clerk, single, American; a typical case of acute pneumonia with pain, fever, quick respiration twelve hours after initial chill; there were also rust-colored sputa toward the end of the first day, when I saw him; this case reacted as some of those described by Dr. Van Zandt, that is to say, the pneumonic process immediately yielded to creosote after twenty-four hours, and the patient was practically convalescent on the fourth day.

II.—Charlotte M., aged twelve years. Patient has lobular pneumonia caused by influenza; had been sick with it for two weeks, no change for the better. The reaction to creosote in this case was just as favorable with regard to fever and other symptoms as I have seen it in cases of lobar pneumonia. She took 10 gr. four times daily for eight days, and the temperature rising no more after that, she was put on small doses of strychnine and an expectorant mixture, given nourishing food, and her lungs cleared up gradually under free mucopurulent expectoration.

III.—Sarah S., aged thirty-two, married, childless, housewife; sick with lobar pneumonia concerning

entire right upper lobe for three days, when I saw her; consolidation well marked; she was immediately put on carbonate of creosote 60 gr. per diem with the same good general result as in all other cases; resolution began in the second week and was complete about the tenth day of illness.

Epicrisis: by the title of this paper is indicated that I mean to show that the carbonate of creosote exercises a remarkably beneficial and uniform influence upon the pneumonic patient. Is the action of this drug such as would justify us in pronouncing it curative? Is it really a remedy for pneumonia? In attending a case of pneumonia our present working theory is about this: the illness of the patient is caused by specific toxins formed through the action of certain pathogenic germs, and that his recovery is dependent upon the speedy production of serum antitoxins, which must be sufficient in quantity and quality to overcome the deleterious action of the toxic substances circulating in the blood. In the majority of cases the system is adequate to the demand, but in a considerable number, at least 25 per cent., it is not, and the patient succumbs. When a typical case of pneumonia ends by crisis, what is generally disclosed by the physical examination made the day after? The patient rests quietly, breathes easily, pulse and temperature are normal or subnormal; the affected lung, however, is found to be in the same state of hepatization as the day before, and the work of resolution begins and proceeds with more or less celerity. Very much the same thing occurs after the administration of creosotal, as we have seen in all the cases cited, and in many more reported by other observers; about 1 dr. of the drug having been taken, the temperature goes down to normal, and the patient feels much better generally. If the drug is now discontinued, the temperature, etc., will go up again; we resume it and continue at the rate of 50 to 60 gr. per day for three, four, five, or six days, and then the temperature will go down and stay down, and the affected lung will begin to clear up.

It must be conceded, I believe, that neither to the antipyretic nor bactericidal qualities of creosote is to be accorded this remarkable and beneficial influence upon pneumonia, a fact which, so far as my experience goes, is never accompanied by any symptoms of depression or disturbance of the gastrointestinal tract. It is reasonable to say that its action must be antidotal to the pneumonic toxins. None of my cases received any other remedy while the illness lasted, except a small dose of Dover's powder for controlling restlessness. All of the hospital cases were more or less advanced when admitted, except one. None were promising so far as the patient's constitution and general antecedents were concerned. Indeed, both Dr. Adams and myself thought that, as cases go, their chances of recovery were by no means good. Yet they all recovered, with the exception of Case IV, who, after being well from the pneumonia as such, succumbed to the deleterious influences of cardiac and probably also hepatic disease, which, I believe, antedated the pulmonary affection. No sooner were the patients under the influence of creosotal than all further anxiety about them appeared to be unnecessary. We visited and examined them twice daily, saw to it that our directions as to nursing and feeding and the exact dosing of creosotal were properly carried out, and had the satisfaction of seeing the patients through the illness without resorting to the usual array of hypodermatic remedies.

It may be urged that, pneumonia being a self-limited disease, even bad cases will recover; so they do, as we all know; but then good and uncomplicated cases die in spite of the best care and the so-called symptomatic treatment because the system does not furnish a sufficiency of serum antitoxins to end the pneumonic process. Unfortunately, we are not in a position to tell in any case of pneumonia whether Nature will be able to do the one thing needful and cure the patient; we must go on, therefore, trying to find a remedy on which we can rely in helping Nature's efforts. These cases and many others have shown, I believe, that creosotal is such a remedy, working in a very similar way to the antitoxins furnished by the system. I should, of course, be delighted to furnish many more positive observations than I have done here, but my term of service began late in the winter, and in private practice we are not apt to see much of pneumonia after April; others, however, have seen and recorded equally good results before me, and being quite in accord with them, I am anxious to bring these clinical records to the knowledge of the profession, hoping that the remedy may be given a fair trial by many during the coming winter, and that the results obtained may be as favorable as my own.

25 WEST FORTY-SIXTH STREET.

ON THE USE OF A. C. E. MIXTURE AND ETHYL BROMIDE IN OPERATIONS FOR ADENOID VEGETATIONS.*

BY J. W. GLEITSMANN, M.D.
NEW YORK.

WHEN I was requested in January by our honored president, to state my experience as to ethyl-bromide anæsthesia before this association, I was under the impression that I was expected to make some short remarks on the subject in conjunction with a presentation by Dr. French. Communicating with the doctor, I learned that, in addition to his demonstration, he was also to speak on other narcotizing agents for the same operation, and that a general discussion would follow our essays. He kindly suggested that I mention also the administration of the A. C. E. mixture, with which he was less familiar, and although I have almost completely discarded it now, I accepted his suggestion.

Before entering upon the subject proper, permit me to state that I took to both anæsthetics in an entirely empirical way—I may almost say, adopted them for the sake of expediency, and made no more scientific observations than those which practice required for their safe application. This was also the reason why I hesitated so long, and was more or less reluctant to yield to our president's invitation. Besides, I was so fully under the impression that everybody was thoroughly familiar with the advantages of ethyl bromide, that I was somewhat surprised to be led to believe that I could present in this subject something of interest and value.

When I said that I adopted both agents originally more for the sake of expediency than for scientific reasons, I may remark that I had to appear twice within a very short period, in 1886, at a coroner's jury, when two colleagues of high standing were accused of having caused death by administration of chloroform at operations. The annoyance of such proceedings, and especially the difficulty of clearing our colleague and the hospital in one case, made it apparent to me that it was useless to expose myself to such vexations and undergo such trials. I cannot state any further reasons why I turned to the A. C. E. mixture instead of to ether pure and simple at that time, but believe it was the lessened

*Paper read to open the discussion on general anæsthesia in operations upon the nose and throat at the meeting of the American Laryngological Association, May 28, 1901.

liability of employing chloroform in the small quantity contained in the compound, and its somewhat more rapid action than that of ether alone. Whatever may be the opinion and experience of others, I was fortunate enough not to have a single serious accident with it, and have employed it after 1894, although less frequently, with the same result. After the year mentioned, I commenced with ethyl bromide, and was induced to do so by the statements of Moritz Schmidt in the first edition of his textbook. Since 1894 I have used ethyl bromide almost to the exclusion of anything else, and have tried to extend its usefulness also to cases in which I had until quite recently used the A. C. E. mixture.

About the latter, in my belief, nothing new or interesting can be said, as you are all familiar with its effects, the length of time required for bringing on, and for the patient to awaken from, the narcosis. It has been my habit, to which I adhere up to the present time, in the few isolated cases in which I give it, to administer the mixture by one of my assistants to the child lying on a couch, until it is thoroughly under its influence, then, by carefully raising it, it is handed to the other assistant, seated in a solid chair and operated upon in the upright position. I never knew, until quite recently, that Dr. French advocated this same position for operations for adenoid vegetations, and it gave me great pleasure to learn that we both agree so well on this point. The only accident I had with the A. C. E. mixture was an attack of suspended respiration when the child was brought to the chair to be operated upon, from which it was quickly revived by the usual methods of resuscitation, and the operation performed. The cause of the collapse was the tight band of a skirt which had not been removed, as the child being claimed by the parents to be extremely nervous, was undressed and narcotized in another room, to save it the excitement of seeing the operator. Since that time I have rigorously insisted that the undressing of the child be supervised by one of my assistants in my presence, and I have had no more accidents of this kind.

In this connection it may be in place to say a few words about assistance—at least the manner in which I proceed in operating. Although I take it for granted that the subject of our discussion is not if an anæsthetic shall be employed at all, but which one we find safest and most useful, I must say here that I use an anæsthetic almost invariably for several reasons, and the exceptions are insignificantly few, only once in a while in grown-up, courageous children with a small mass of the growth in the middle of the nasopharynx, and amount to not more than two in a hundred cases. I give anæsthesia, especially since employing ethyl bromide, in my dispensary and clinical, as well as in my private practice, the small loss of time being more than outweighed by the possibility of making the operation thorough, by saving the little patient pain and shock, and thereby not losing his confidence, which may become an important factor if in the future other manipulations are necessary. The assistants I employ in private practice have been the same for many years past, and they, by their repeated experience, have acquired such a technique and dexterity in undressing the child, in narcotizing, holding the child in the proper position, and making the necessary movements of the head which I deem expedient and advisable, that I have to exert very little or no supervision at all, and can give my whole attention to the operation. I am free to confess that it is due as much to their faithfulness and efficiency as to my own doings that I never had a fatal or even alarming accident in the large number of cases I have operated upon. I have in late years even dispensed with the services of the family physician, who, for courtesy's sake, had to be invited to be present, and whom I then requested to attend to minor details. I feel the difference very keenly when I have to operate at one of the hospitals with which I am connected, where the assistants shift every three months, and where in consequence the operation is more laborious and not as quickly and smoothly performed. As also the manner and method of operating is no topic of our discussion, I shall mention only briefly that I have, without a single exception, made all my operations in the upright position; that I never hesitated to operate the severest case in the manner indicated in my office; that I have never sent a child with adenoids to the hospital for the purpose of operating alone, and that I operate children at their parents' house only at their request, or for extrinsic reasons.

As said before, I adopted ethyl bromide in 1894, and, becoming more satisfied with it the longer I use it, have employed it lately also in cases where I gave A. C. E. mixture formerly, viz., when I operate at the parents' house. It was probably merely from force of habit that I adhered to the A. C. E. mixture on such occasions, and I was very glad to notice the delight of the parents when the child woke up from the narcosis so quickly after ethyl bromide. It was primarily the desire to have an agent which did not compel the child to remain so long at my office to get over the narcosis that made me change from A. C. E. to ethyl bromide for office practice, and as much as I encouraged the parents formerly for the above reason, to have the operation done at their house, I now rather advise them to bring the child to my office, thereby saving a great deal of time. My highest record is seven operations in one day—two at my private office and five at my clinic, which latter could not have been accomplished with any other anæsthetic in the time at my disposal.

I confined my researches of the literature to the publications quoted in the sixteen volumes of Semon's *Centralblatt* from 1884 to 1890, but shall not weary you with their enumeration. I further saw no mention of the subject in the transactions of our association, but found that three of our members, Drs. Roaldes,[1] Hardie,[2] and myself,[3] had spoken or written about ethyl bromide, and that a fourth member, Dr. Hinkel,[4] had reported to this association a death from chloroform in adenoid operation. On April 11, 1894, a meeting of the London Laryngological Society was held to discuss the choice of an anæsthetic in operations for adenoids, called on account of the unpleasant number of deaths from chloroform having occurred of late in England. Although about one dozen publications on ethyl bromide had appeared up to that time, I did not see it once mentioned in the original report contained in the *British Medical Journal* of the same year,[5] and the same holds good in a much later series of American essays on Selection of Anæsthetics in Surgery (*Journal of Am. Med Assoc., March* 24, 1900). Shortly before the English meeting, Dr. E. Meyer gave at length his views and experiences in 250 cases before the Berlin Laryngological Society,[6] followed by a similar discussion by several gentlemen. On the basis of 250 cases, Meyer claims that the agent in doses from 10 to 15 grms. is harmless, that anæsthesia takes place within twenty-five to sixty seconds and lasts a minute and a half to two and a half minutes with unpleasant after-effects. Grabower warns against its use in anæmic children, while Rosenberg, the last speaker, saw no danger even in delicate and very young children. Hardie also considers it contraindicated in nervous, timid children. Hardie, in his excellent essay, quoting from Morgenthau, writes

further on the physiological effect of the drug, saying that the cardiac alterations are much less than in chloroform narcosis, and that the bromide has only a slightly depressant action on the heart. He gives the death rate from bromide to be two in 7,541 cases, one, however, occurring in Billroth's clinic in a patient with heart disease, which could, without unfairness, be excluded. Roaldes' paper is very thorough, goes back to the year of its discovery, 1829, by Serullas, and he states its advantages and disadvantages very concisely. As to the latter, its action on the glandular system, exciting hypersecretion, and its tendency to produce muscular contractions, never interfered in any of my cases. That it is unsuited for prolonged operations, and that an absolute purity of the drug is required, is a matter of course.

About the degree of the anæsthesia to be reached, and consequently the quantity of the drug used to produce it, the authors differ somewhat; Texier,[1] for instance, being afraid of unpleasant effects, advises against a complete narcosis and operates in the stage of analgesia preceding it. He never gives more than 5 to 10 gms. to children of eight to fifteen years of age, and leaves the mask *in situ* fifteen to thirty-five seconds—never longer than forty seconds. But I believe the majority of operators follow the example of Moritz Schmidt,[2] who prefers complete anæsthesia, and begins with pouring 10 gms. into an impermeable mask. When bromide is gradually added, narcosis takes place within two minutes; but although generally less than 30 gms. are required, he had the same experience in exceptional cases, like myself, that 40 gms. were necessary to produce complete anæsthesia. Schmidt, in his second edition, enumerates five deaths from ethyl bromide, but believes them due to cardiac complications. As far as my individual experience goes, I never had a serious or alarming accident at the many operations I performed. I regret not to be able to give you accurate statistical data, but inquiries at the three institutions with which I am connected, and questioning my private assistants, I can safely say that the number of five hundred operations under ethyl-bromide narcosis is rather under than over estimating the aggregate. Among these I had only two cases where the narcosis had to be interrupted for a short time, on account of irregularity of respiration; in one case, a secondary hemorrhage occurred several hours later at the child's home, controlled by the family physician; and once I had a case of sepsis, manifesting itself in an inflammation of the knee and ankle joint, which kept the child ill for four weeks and was wrongly attributed by the father to an undue pressure against the knee by one of my assistants while holding the child in the proper position.

I conclude by giving you in as condensed a form as possible my method of operating, from which the experience of years has taught me not to deviate, if the result is not to be jeopardized or unnecessary annoyance caused to the operator:

As stated before, I use an anæsthetic, and now ethyl bromide in such a preponderance of cases that the exceptions can be disregarded. Further, I always employ two assistants, and in my private cases one holds the child in position, the other giving the bromide, and later holding and steadying the child's head. Formerly, when operating in the hospitals to which I am attached and in the parents' house, I did so with diffused daylight, seating the child opposite and near the window of a well-lighted room, but found lately that in a dark room, with the reflected light from a head mirror, I could overlook the field of the operation better, and I now make my arrangements accordingly. After the child has been brought to the room, all the constricting garments removed under the supervision of one of the assistants, the heart examined, and a loose gown thrown over the child, it is handed to the other assistant, seated on a solid chair, and the narcosis begun. The mask I use is intended to and does exclude the air almost completely, and is tightly pressed over the child's nose and mouth. Merck's one-ounce glass tubes serve the purpose admirably, giving very little waste; and the administration is continued under control of the pulse until the muscular tonus is abolished. The introduction of Denhard's mouth-gag at this period generally rouses the child somewhat from its stupor, into which it soon relapses after a few more whiffs of the bromide. The narcosis is now deep enough and will last sufficiently long to allow, with a moderate amount of dexterity, the removal of both tonsils, and of the adenoid vegetations, if such be necessary. I have no ironclad rule laid down for myself, which of the two I remove first, if both be present; but I am guided by the condition of the individual case. The vegetations I removed in years gone by alone with the post-nasal forceps which bears my name, then with the curette (Gottstein's model) exclusively; but finding that I had by the latter method a few recurrences of the growth, I now use first the forceps, removing the larger part of the masses, and then with the curette the remaining ridges. So far I am satisfied with the result obtained in this manner. As a rule, I do not make all these manipulations without an interruption. After tonsillotomy, I assure myself if there is no undue bleeding, and if such, arrest it by manual pressure with a napkin dipped in weak carbolic solution sufficiently, before commencing with the adenoids. For the latter, I enter the nasopharynx four or five times with the forceps without changing the child's position; but then my assistants are trained at the moment of request to lower the child's head rapidly to such an extent that the pelvis is a little higher than the head, which allows a free outflow of the blood from nose and mouth into a suitable vessel without entering the larynx. Here it may be remarked that, when entering the nasopharynx with the forceps or curette, the child being under complete narcosis and manifesting no signs of pain, not all reflex is abolished, the pharyngeal muscles contract slightly and respiration is momentarily suspended the same as when we examine the larynx of a refractionary patient who is not yet trained. While the child is in this lowered position, I make a digital examination to see if anything and what has still to be removed; the child is raised again, and forceps or curette once more applied. Seldom more than two or three introductions of the instrument are necessary, interrupted by lowering the child for the outflow of blood; and when convinced that the nasopharynx is clear, the mouth-gag is removed, the child laid on a couch and left there until sufficiently recovered to be taken home. In the majority of cases it cannot be prevented that some blood runs down into the lower pharynx and reaches the stomach, which is proven by the vomiting of blood when children recover from the narcosis and change their recumbent position. But I never witnessed the inflow of blood into the larynx or trache, acough, or any subsequent pulmonary symptoms having never occurred in my practice. I cannot give a positive explanation for the fortunate absence of this complication; it may be the slight recumbent position of the child leaning against the chest of the assistant during the operation, which makes the blood flow along the posterior pharyngeal wall, but in my opinion the quick lowering of the child's head plays the more important part.

I was perfectly aware that I could not relate anything new or of importance to you, but I shall be per

fectly content it some of my remarks will assist you to make the operation with greater comfort to yourselves and with satisfactory results to your patients.

NOTES ON VIENNA HOSPITALS.*

By JOHN E. SOMERS, M.D.
CAMBRIDGE, MASS.

THE question is very frequently asked by medical men, Where is the best city in which to do post-graduate work? To discuss this subject intelligently, one must needs have some personal knowledge and experience in the various medical centers, in order that his advice may be of value and benefit to those seeking such information. While I cannot lay claim to any extended knowledge in this direction, still I have had some experience in a number of different cities. On this side of the water we have New York, which is admittedly the leading medical center for post-graduate work.

One can do excellent work in New York in the dispensary connected with Bellevue Hospital, in the Knapp Clinic, in the Carnegie Laboratory, and in the various other dispensaries, by taking private courses, or by joining either of the post-graduate schools. There is an abundance of clinical material in New York. Of this there can be no question. New York leads the procession of cities in the United States as a post-graduate teacher.

The number of men in the courses of the post-graduate medical schools, however, precludes the possibility of a sufficiently close contact with the patient, or rather the opportunity to examine personally a sufficient number of cases each day. The private courses are expensive, when given by the best men. We must not forget, however, that it costs something to cross the Atlantic and return, and this we must add to the cost of our study abroad.

Boston offers most excellent opportunities for post-graduate study. The serious objection is that they are not suited to the requirements of the practitioner in Boston or suburbs, being too near the seat of his professional labors. London has the largest amount of clinical material at the disposal of the medical man of any city in the world. It has, however, many serious disadvantages, chief among which are the largeness of the city and the lack of organization for such work. Paris stands in the front rank so far as the brilliancy and eminence of her medical teachers are concerned. The work here is fairly well systematized in many lines. One will always find the men with whom one comes in contact in hospital, in clinic, or in the regular private courses, extremely courteous.

Berlin offers many advantages to the seeker after post-graduate knowledge. She has some very able medical men within her confines, who do grand work as teachers, both in medicine and surgery. My impression is that it costs slightly less to live in Berlin than in the other continental cities.

Of course, in many of the smaller cities, in some special line, one can often find excellent opportunities, as, for instance, in Prague, Halle, or Dresden. But for universal and complete organization in all lines, for teaching purposes, no city can equal Vienna.

This seems to be the consensus of opinion among the most experienced post-graduate workers whom one meets from time to time. In every line of original research, in chemistry, in medicine, and in surgery, one can here find better opportunities, and apply himself more advantageously, than in any other medical center.

Competition in the practice of medicine is very keen in Vienna, and so the men connected with the University have found it to their financial advantage to organize courses in every department of medicine and surgery, to promote the work in every way feasible, and to encourage the advent of as many students to their city as possible.

Many of the professors, assistant professors, and instructors in the University devote a large portion of their time to the giving of private courses. The courses vary in price from eight to twenty-five dollars, making an average of ten or possibly twelve dollars. Some rules can be laid down, which will do the beginner, or new man, no harm to follow. First, always avoid overcrowded courses. By that I mean those having too large a number in them for the amount of clinical material to be handled. Second, when feasible, always enter a course as an observer, for one or two sessions, to ascertain the amount of work at the disposal of the men already in the class, its character, the number of men in the course, the methods of teaching employed, etc. Third, find out something of the medical man giving the course, as to his teaching capacity, etc. For we all know that the ability to impart knowledge in the best manner is not a gift inborn in all men.

The best of the regular or standard classes are always rather difficult to enter. It is well to form, as speedily as possible, a large acquaintanceship in and around the hospital. By so doing, one will find that an opportunity very frequently presents itself to fill a vacancy caused by a man, for some reason, dropping out of a class. This is constantly occurring. New courses are from time to time advertised on the bulletin-boards, from which the student can, as a rule, select what he wants. Four, five, or more men can come together, start a class, and secure the services of a suitable instructor. It is better not to take too many courses at one time. A smaller number properly handled, and assimilated, is better than a larger number indifferently done. The "boss" has arrived in Vienna, I regret to say. Usually a man or a combination of two or three men have ingratiated themselves into the good graces of some of the teachers and practically control many of the best standard or regular courses. They dictate as to who shall or shall not enter these classes. They are essentially the counterpart of the mercantile boss who forms a financial trust, or the political bosses who corral a few thousand votes in one of our municipalities. These little intellectual, self-constituted leaders, fresh from their mothers' knee in some obscure New England town, or some other part of our glorious country, have suddenly acquired greatness. They form a classic trust, and dominate the situation. These medical prodigies had better return to their native hamlets and learn the first principles of brotherhood, justice, and fair

*Read before the Cambridge Medical Improvement Society.

play. I believe attention has never been called to this serious injustice before. The doing so now will probably not remedy the matter. This being my second trip to Vienna, I am quite well acquainted with the people and the happenings in the hospital world there from day to day. I was not a personal sufferer. It is an abuse which has, owing to existing conditions, crept in and fastened itself securely upon the shoulders of the medical man doing post-graduate work there. It cannot easily be dislodged.

A number of special courses are given in just one subject. For instance, a most excellent one is given by Dr. Hammerschlag, first assistant to Professor Politzer in his clinic, and one of the instructors in the University on operations on the mastoid. He teaches on the cadaver, the methods of opening the antrum and the attic, the removal of the ossicles, the exposure, hypodermic puncture, and incision of the lateral sinus.

Of course, Professor Schwartze of Halle is the recognized authority and teacher on this subject in Europe. I am informed that his courses are very expensive and that engagements to come under his instruction must be made many months in advance.

Professor Zuckerkandl gives a very practical and instructive course on the bladder, teaching the use of the electric cystoscope, local applications, operations on that viscus, etc. This is a good one for those interested in that line of research.

Professor Latzko also gives a grand course on diseases of the bladder, in electric cystoscopy, etc., from which much may be learned. A fine course is also one by Dr. Latzko on diseases of women to which only three men are admitted. This includes a touch course with a superabundance of clinical material, local applications, and treatment, massage, minor and major operations. This is by all means one of the best courses in Vienna. It is not my purpose to deal largely with descriptions of the various courses, as that would occupy too much time and space. Professor Mikulicz has temporarily succeeded to the chair of clinical surgery occupied by the late Professor Albert. He has in him the happy combination, rather rare I think, of fine talent and originality with wonderful teaching ability. Let one look in and hear him, if one has a spare moment during the day, and I am sure there will always be carried away some valuable point. Professor Albert died two days after my arrival in Vienna—mourned by the city of his adoption, the whole profession, and the great University which he adorned for so many years. He was regarded as being one of the ablest men in the whole institution. At a memorial meeting of the Vienna Medical Society I listened to a brilliantly prepared eulogistic tribute read by Professor Gussenbauer, on the life and work of Albert. The meeting was called to order by the President; the paper was read, and the meeting adjourned. No business was transacted. This fact made the tribute all the more touching and delicate.

The general hospital was erected in 1770 by Joseph II. The building is now old and unsuited to the requirements of modern medicine and surgery. Many of the clinic and operating rooms have been, as far as possible, modernized by the introduction of mosaic floors and other improvements. The operating amphitheater, made memorable by the illustrious Billroth, has been recently enlarged and much improved, but is still too small. It is in contemplation to raze the present hospital and convert the grounds into a public park, the idea being to erect a new and larger hospital on the grounds at present occupied by the insane asylum not far away. These grounds cover a much greater area and would consequently permit of the erection of a larger building with more ample grounds about and surrounding. The insane asylum would in turn be removed to the outskirts of the city. The lack of money is the only thing that now delays the project.

The Rudolph Hospital, erected in 1865, with a capacity of 1,000 beds, is located in the fourth district of the city. It contains one of the most extensive, well-equipped, and complete laboratories for original research to be found in Europe. Antitoxin is here manufactured on a large scale. Original investigation is carried on most extensively in chemistry, bacteriology, and pathology. Experimentation with the newer antitoxins has also a large place in this work. In connection with these laboratories is kept in outbuildings a very large collection of animals, such as horses, cows, calves, dogs, goats, sheep, guinea-pigs, and poultry of many varieties. The institution is supported by the State, and one studying in Vienna or passing through that city should visit this plant, feeling assured of the most courteous treatment. To see it to the very best advantage, however, an introduction to the superintendent of the hospital would be a *sine qua non*. One can easily make arrangements, if so desired, to become attached to any of these laboratories as a student or assistant. The Kaiserin Elizabeth Hospital, situated in the fourteenth district of the city, has also a capacity of 1,000 beds. The newer part, or Bottini pavilion, is modern, well arranged, and supplied with all conveniences necessary to do first-class aseptic surgery. The basins for cleansing purposes in the operating rooms here (as well as those all over Vienna) are fitted with pedal-faucets. They are usually four in number, one each for hot, cold, and lukewarm water, and for escape. A portable electric-light stand in the operating room in the Bottini pavilion, about four feet high, struck me as a very useful adjunct to the work. The lower two feet were solid, the upper two flexible, constructed of block tin, and covered with a spiral copper wire. The result is a light which can be moved about the room at will, and which can be twisted around to the right or left shoulder, in front or behind. It can be utilized, of course, only in cases in which the operator sits down, as in operations done per vaginam. There are, on the four sides of the room, electric fixtures to which the wire can instantly be attached, so that the wire supplying the current can, at a moment's notice, be shifted from one part of the room to another.

The "Schleich" solution for local anæsthesia, which is much used in Vienna, consists, as is now well known, of morphine sulphate gr. ½, cocaine hydrochlorate gr. 1, sodium chloride gr. 2, and water ℥ 2. It is without question an excellent preparation. I saw an abdominal section done with it very satisfactorily indeed. The solution is first injected into the cellular tissue, and later, when pain exhibits itself, a small piece of sterilized absorbent cotton wound around the end of a wooden handle, about six inches long, is dipped into the solution and rubbed into the wound. Since my return, I have tried it in three minor cases with very pleasing results. Of course, one can use this solution in much greater strength than that mentioned, if so desired. The "Schleich" solution for general anæsthesia, which is also quite extensively used in Vienna, has, I believe, no advantage over ether or chloroform. I had the opportunity to watch the process of anæsthetizing patients with it in a large number of cases. The proportions are the following: Sulphuric ether gm. 500, petrolic ether and chloroform each gm. 250.

Experimental work in the treatment of lupus with the Röntgen rays has been and is still carried out on an

extensive scale. It is a curious feature that of the two principal investigators in this field, one reported brilliant successes, while the other reported almost complete failures. As a result, a hot controversy was being waged between the two men when I was in Vienna. We must all hope that the former may yet be able to sustain his position.

Osteomalacia, which is much more common in Europe than in this country, has, as a result, been more carefully studied there than on this continent. Dr. W. Latzko of Vienna has, perhaps, done more original work on this subject than any other man in Europe. With us this field, no doubt, presents not much more than a scientific interest, but it is certainly a very fascinating subject from that point of view. It occurs, as a rule, among married women. The symptoms most frequently encountered are narrowing of the angle of the pubic bones, curving in of the wings of the ilium, antero-posterior narrowing of the pelvis, curvature of the femur and other bones, spontaneous fractures, and inability to abduct the thighs. On moving an object downward in front of the eyes, and having the patient follow it, it will be found that the lids drop not gradually, but by jerks. The lifting power of the muscles of the thigh is much diminished, as noticed when a patient attempts to ascend a flight of stairs. This she cannot do without grasping the banister for assistance. Slight shortening of the body is a not unusual symptom. I saw one case in which there was a shortening of four inches. So great an amount is exceptional. It was my good fortune to see a large number of these cases in a clinic for diseases of women. I am inclined to think that an occasional case passes us in this country unrecognized. Phosphorus is the most successful drug for use in these cases. Great success has been attained by this plan of treatment.

I made some records of the temperature of the operating room at the Kaiserin Elizabeth Hospital at the time of operation. I found that the average temperature at which operations were performed was 18° Celsius, equal to $64\frac{2}{5}$° F. It seems to be, in this country, a universally accepted belief that higher temperatures than those mentioned are necessary in the operating room.

Gloves are not used in operating. Retractors are not employed in abdominal work. In abdominal operations, silk is the almost universally accepted ligature. Quantities are buried in the abdominal cavity without the slightest hesitation, and without any untoward effect. It is done with confidence—a confidence born of a long experience. The whole secret of success lies in the complete asepsis of the silk used. I asked Professor Wertheim why he did not use kangaroo, as advocated by Dr. H. O. Marcy, in America. His answer was that he was afraid to do so on account of the difficulty, as he believed, of aspepticizing it.

Conservatism is a great virtue, and the Germans possess it in marked measure. There is practically only one method of closing an abdomen in Vienna, and that is by sewing each layer separately with interrupted sutures of silk, cut very close to the knot. The first or peritoneal layer is done with a very fine silk. The majority of the operators do not seal the wound, although exceptionally this is done. On further observation, I am convinced that the aseptic and antiseptic work in Vienna is most thorough and in many ways most excellent. There are, however, some serious objections to the methods employed for the production of aseptic conditions in the patient. A newcomer, I think, would be struck by their excessive care in washing the hands and arms—a very laudable excess, sometimes not practised to the extent it might be in our own country. The only antiseptic for the hands employed is corrosive sublimate 1 to 1,000. Permanganate of potassium and oxalic acid are not used. To produce an aseptic vagina, sterilized soap and sterilized water, alcohol, ether, and corrosive sublimate are each in turn employed. The strength of the sublimate solution for this purpose is usually 1 to 1,000. The abdominal wall just prior to operation is treated in the same manner, and the patient is allowed to lie in this wet condition during the operation. The abdominal cavity is almost never washed out with normal salt or any other solution. A 50-per-cent. solution of chloride of zinc is one of the applications commonly used in cases of endocervicitis. Two, 3, and 4 per cent. solutions of silver nitrate are employed in gonorrhœal urethritis in the female, beginning with the 2-per-cent. solution. In cases of curettage, the uterus is packed with a strip of iodoform gauze about half an inch wide, and woven on both edges. The treatment of retrodisplacement of the uterus with moderate adhesions, when there is no contraindication, is by putting the patient under an anæsthetic, tearing up the adhesions, bringing the uterus forward, and inserting a pessary. This is followed by massage, and when the latter is systematically carried out, the treatment many times results in a cure. When this fails, or, for any reason, when fixation is indicated, a vaginal operation is more often done than a ventrofixation. The vaginal fixation is preferred on the ground that this method does not interfere with pregnancy. Of course, in many cases only a ventrofixation is possible.

By the courtesy of one of the members, I attended a number of medical society meetings. At one of these, I listened to a discussion in which Professors Wertheim, Latzko, and Schauta participated. The subject for discussion was recurrence of the disease after hysterectomy for cancer of the cervix. Wertheim stated that he had had 32 per cent. of recurrences; Latzko, 14 per cent.; Schauta had no exact statistics to offer. These are three of the leading gynecological operators of the city. They all have extensive clinics. Wertheim has charge of seventy gynecological beds at the Kaiserin Elizabeth Hospital. He operates mostly by the abdominal route, and in all cases, as far as possible, extirpates the glands and surrounding tissue. He gives the cervix no preparation outside of its asepsis. Latzko operates chiefly by the vaginal route. He prepares the cervix by thoroughly cauterizing it with the thermocautery, and, when the necessity demands it, he also curettes the cervix prior to cauterization. He also makes his primary anterior and posterior incisions by means of the cautery. I believe this to be a wise procedure. It is quite noticeable in Vienna that there is a marked tendency to readopt the abdominal route. Indeed, this is true of all the countries of Europe. Especially is it true of France, the former home, the strong advocate, and, I was almost going to say, the originator of the vaginal method of hysterectomy. On the other hand, there is a tendency upon the part of the Vienna surgeon to do more and more of the adnexal work per vaginam. I am convinced that this is well, for a large percentage of the extrauterine pregnancies, large ovarian tumors, resections of the tubes, salpingotomies, ignipunctures, resection of cystic ovaries, etc., can be as well, and perhaps better, done through the vaginal than by the abdominal route. It is a curious phase of the subject that, only a very few short years ago, the Continental surgeon looked upon the American with an eye of pity and something bordering upon a sneer, because the American surgeon, in his assumed ignorance, had dared to practise and teach the advisability of the abdominal in preference to the

vaginal method of hysterectomy. And some of their operators, in their pity and sympathy for the benighted American surgeon, even graciously consented to and did come over to teach us the vaginal method, and to lift us from our condition of deplorable ignorance. What the American surgeon then taught is now being gradually recognized all over Europe as the preferable operation in the majority of cases. I have no hesitation in expressing the belief that there is as good surgery done in America as in any part of the world.

THE PATHOLOGY OF BRIGHT'S DISEASE.*

By GEORGE E. DAVIS, M.D.,
LAWRENCEBURG, KY.

PATHOLOGY is the doctrine of disease, and signifies a morbid change, either in exercise of functions or in texture of organs. By Bright's disease, pathologically speaking, we usually understand a morbid change in the texture of the kidneys so material as to modify or suspend their function, whose office in the animal economy is, eminently, elimination. Our discussion, on account of limited time, shall be nearly confined to this narrow field. However, we should not be deluded, for the pathological domain of Bright's disease is so broad that it involves lesions of texture and derangements of function, more or less, of the whole organism. In fact, the toxins, which the kidneys fail to separate from the blood, not only primarily poison the blood, but make it a vehicle to reach all the other tissues and do them injury.

An accurate knowledge of the pathology of Bright's disease is absolutely essential to an interpretation of the symptoms and correct treatment. But it is necessary to acquire a knowledge of the physiology and histology of the kidney to gain a clear conception of the pathology. Briefly, the physiology of the kidney is to eliminate from the blood various toxic substances which result from normal metabolism, as well as foreign toxins that may have gained entrance. The study of the histology of the kidney is a study of the mechanism by which said elimination is accomplished. The kidney may be likened to a double filter, or to a filter with double or two funnels. A filter or *filtrum* is any porous material through which liquid is passed to separate it from matters suspended in it. To filter, then, is to purify liquor by passing it through an apparatus which separates any extraneous, impure, or feculent matter. The filtrate is the filtered or purified liquid. In the present application it is the *blood* in the renal vein and not the *urine*, as indicated by some authors. No less an authority than Brunton[1] misapplies the term "filtrate" in this connection. The blood which is to be purified is conveyed to the kidney through the renal artery, and returns from it through the renal vein, filtered and purified. The impure products of tissue waste and extraneous matter pass out through the uriniferous tubules. Therefore, the structure of the kidney, whose function is to purify and purge the blood, represents a filtering apparatus. The arterial capillaries or glomeruli, the capillary plexus of veins, the uriniferous tubules, and the lymphatics constitute the porous material; the fibrous capsule, inclosing the kidney, is the container of the porous material; the renal vein represents one funnel, returning the filtrate or purified blood; the ureter represents another funnel, conveying, from the kidney to the bladder, in watery solution as urine, the extraneous, feculent, defecated impurities separated from the blood. The arterial capillaries are derived from an afferent branch of the interlobular artery, which is a branch of the renal artery, and are disposed in coils, forming glomeruli or tufts, surrounded by a capsule (Bowman's), which begins the uriniferous tubule. This arrangement of capillaries in glomeruli is for the double purpose of gaining greater surface and securing increased blood-pressure to facilitate the mechanism of filtration. Bowman's capsule is the beginning of a long convoluted tube, lined with epithelium, whose function is the final transformation of the tissue waste-products of metabolism, or the secretion of the solid constituents of the urine.

This epithelium serves another and equally important, though negative, function, viz., under physiological conditions it prevents the escape of serum-albumin and other normal constituents of the blood. The filtering and secreting capacity of the uriniferous tubules is not only increased by their length and convolutions, but their caliber, having several alternating dilatations and constrictions, retards the flow of the fluid to be filtered, and permits more time for completion of function—no small favor to a crippled or overworked kidney.

The uriniferous tubules are surrounded by lymphatics and a capillary plexus of veins, the latter emanating from the efferent arterioles of the glomeruli. The purpose of this structural relation is to provide further opportunity for the action of the renal epithelial cells. These cells absorb any excess of water or superfluous salts that may have filtered into the tubule through the glomeruli, and give them back to the lymphatics and veins, to be returned to the organism to serve other vital processes in the economy. These cells also absorb from the lymph spaces and the venous plexus the products of disassimilation or tissue-waste, most of these having been already transformed into urea by the liver,[1] and complete the transformation or secretion, which is excreted as the solid constituents of the urine.

This brief review of the physiology and histology of the kidney is given, not with the view of drawing fine theoretical distinctions of the different forms of Bright's disease, but simply as a practical aid in studying the pathological changes in the structure, and in interpreting the characteristic clinical phenomena occasioned by those morbid changes, in their usual sequence of occurrence, to wit, albuminuria, dropsy, and uræmia.

Albuminuria.—Before we get true albuminuria, a morbid change in the vascular walls of the capillaries and the epithelium of the tubules is absolutely essential. Experiments have proven that increased pressure-effects alone are not sufficient cause. Ligation of the aorta below the renal arteries, notwithstanding it greatly increases blood-pressure in the glomeruli, does not produce albuminuria. Why? Because nourishment is amply provided by the increased blood-supply, and while the increased blood-pressure increases the positive function of the kidney—that of secretion—it does not impair its negative function—that of preventing the escape of serum-albumin so long as nourishment is supplied and the renal tissue remains normal. Moreover, the increased pressure in the glomeruli is compensated by the collateral circulation in the kidney. There are three channels by which the blood may reach the renal vein without passing through the glomeruli. First, the terminal branches of the renal artery anastomose with the stellate veins beneath the capsule on the surface of the cortex; second, branches direct from the interlobular arteries, together with branches given off from the

*Read at the annual meeting of the Kentucky State Medical Society, held at Louisville, May 22–24, 1901.

[1]Brunton, "Disorders of Digestion," 1803, p. 316.

[1]Davis, MEDICAL RECORD, September 15, 1900, p. 415.

afferent arteries before they reach the glomeruli, anastomose with the venous plexus surrounding the tubules; and third, the arteriæ rectæ anastomose with the vasa recta. Through these three channels the blood-pressure in the glomeruli is relieved. However, when the renal vein is ligated, we do get albuminuria. The explanation is that the blood-supply being stagnated, nutrition is deficient, and the texture of the renal structure is changed. Increased blood-pressure under these conditions will cause albuminuria. The pressure is first felt in the venous plexus and then in the glomeruli, and being little or not at all compensated by collateral circulation—the blood having no avenue of return to the system—the albumin that is poured out into the lymph spaces surrounding the tubules cannot be absorbed by the venous plexus on account of increased internal pressure, nor can it re-enter the glomeruli for like reason; therefore, it is forced into the tubules to escape with the urine. Venous congestion, then, does cause albuminuria; but there must first be a lesion in texture before it is operative. I wish to note here that the venous congestion of Bright's disease is due to a weak circulation. The soft, feeble pulse is what we have to fear, and not the wiry, high-tension pulse of arteriosclerosis. The latter often is a complication, being produced probably by the same agent that caused the Bright's disease. The cardiovascular change produced by Bright's disease is one of degeneration, and results in a weak heart and a soft, compressible pulse, which must not be confounded with the rigid, wiry pulse of arteriosclerosis, that not infrequently complicates the incipient stages of chronic Bright's disease. I wish to emphasize this differentiation.

Dropsy.—The presence of fluid in the cellular tissues, *i. e.* œdema or dropsy, is influenced by three conditions, (1) alteration in the composition of the blood; (2) alteration in the structure of the capillaries; (3) alteration in the vasomotor nerves which control the capillary circulation. Normally, there is a constant exudation of fluid from the capillaries into the lymph spaces to supply nutriment to the cells of the various tissues of the body; and after it has served this function it is reabsorbed by the veins and lymphatics. Under physiological conditions the exudation and absorption are equal, but when from any cause the exudation is increased and the absorption is decreased, an accumulation ensues. If it occurs in the cellular tissue it is termed œdema, but if in a serous cavity it is called dropsy.

1. Alteration of the blood, or anæmia of Bright's disease, is caused by albuminuria. Serum-albumin, which is one of the most important ingredients of the blood, escapes with the urine, instead of remaining to minister to the nutrition of the blood and body. The red blood cells suffer, too; for hæmoglobin contains not only hæmatin, but also an albuminous substance—globulin—and the latter not being supplied, the blood is further impoverished. Albuminuria, then, by causing anæmic or watery blood, proves a pathogenic factor in dropsy, but hydræmia alone is not sufficient to produce dropsy if there is not an alteration in the capillaries first.

2. Alteration in the texture of the capillaries, however, renders exudation through them more easy, and, after all, the main factor in the pathogenesis of dropsy resolves itself into the condition of the capillary vessels. Experiments of rendering the blood watery, by intravenous injection of large quantities of decinormal salt solution, have proven that exudation is not increased so long as the capillaries are in a healthy condition. Capillaries altered by inflammation or lack of nutrition are rendered more permeable, and then any alteration of the density of the blood, by dilution, is quickly manifested by increased effusion. Diluted or hydræmic blood does not pass through healthy capillaries more readily than does normal blood, yet it effuses much more easily through altered capillaries. Therefore, albuminuria not only alters the blood, but through the blood-change alters the capillaries, and when the structure of the vessels is altered, hydræmia greatly increases the œdema.

3. Alteration in the vasomotor nerves influences the pathogenesis of dropsy. Exudation takes place slowly and absorption rapidly when the vasomotor nerves are acting powerfully, and, on the other hand, exudation takes place rapidly and absorption takes place slowly when the vasomotor nerves are acting feebly. Vasomotor weakness, then, favors dropsy in a double manner, by both increasing exudation and retarding absorption. Albuminuria causes the vasomotor weakness by withdrawing nutrition.

To summarize the pathogenesis of dropsy, we may state briefly that albuminuria, by withholding nourishment, produces (*a*) an alteration in the composition of the blood, or anæmia and hydræmia; (*b*) an alteration in the texture of the capillaries; (*c*) an alteration in the condition of the vasomotor nerves which control the circulation, the exudation, and the absorption by the capillaries.

Uræmia.—A full discussion of the pathogenesis of the complex morbid phenomena of Bright's disease, hidden under the term uræmia, especially implicating the nervous system—both sensory and motor—and complicating the muscular, respiratory, circulatory, and gastrointestinal systems, also involving special organs as the eye, skin, liver, etc., cannot be embraced in so short a paper. The organism in its normal, as well as in its pathological, state receives and forms poisons, and the renal function affords the chief means of getting rid of them, as the kidney can eliminate all toxic products except gas.

Uræmia is a mixed form of poisoning, due to many causes, and we cannot offer one explanation alone for all the accidents of bad repute which may appear in the course of Bright's disease. Several pathogenic theories have been invented, seeking to identify these accidents with certain anatomico-physiological conditions, appealing to clinical observations to justify themselves. One investigator has incriminated urea as a cause of uræmia; another has invoked cerebral œdema as an explanation; some accuse ammonia; others, again, claim that potassium, coloring matters, and extractive substances, such as uric acid, creatin, leucin, xanthin, etc., precipitate all the accidents of uræmia. All these theories may possess an element of truth, for the most rational explanation of uræmic phenomena, and the one most in harmony with clinical and experimental observations, is that they are produced not by any single element of the retained waste products, but by the entire mass. An analysis of normal urine reveals the presence of several poisons, which render it difficult, if not impossible, to differentiate and estimate the pathological potentiality of any particular one, two, or more of these poisons that the kidneys may fail to eliminate. What is of more import to the clinician is to remember that to invoke uræmia, it is not sufficient that the kidneys should be diseased. It is essential that there should be so great a lesion of texture that its functioning power is decreased to such a degree that it cannot eliminate in twenty-four hours the amount of poison which the organism forms in that time. When we consider that the utmost capacity of the normal kidney for twenty-four hours compared to what it ordinarily secretes in that time is in the ratio of about ten to one, we can appreciate the degree that it may be pathological in structure and yet, clinically speaking, be physiological in function. This observation em-

phasizes the unreliability of urinary tests alone in the diagnosis of Bright's disease, for a kidney may be markedly diseased, and the urine remain normal in quality and quantity. However, under these conditions, complications of other diseases may precipitate intoxication, therefore frequent urinary tests and a close vigil for other clinical manifestations are necessary, if we would not reproach ourselves for serious and fatal accidents, the outcome of intoxication arising from the suppression of the renal function to which we apply the term uræmia.

Lawrenceburg, Kentucky.

A REPORT OF SOME CASES PRESENTING GROSS LESIONS OF THE BASAL GANGLIA.

By M. L. PERRY, M.D.,
MILLEDGEVILLE, GA.,
PATHOLOGIST TO THE STATE SANITARIUM.

During the past year a number of cases presenting gross lesions of the basal ganglia have come under my observation. The three following cases show lesions of such importance, involving three much studied, but as yet poorly understood, parts of the brain, that I believe a report of them will be of interest and value in furthering our knowledge of the anatomy and physiology of these organs.

Case I.—Acute Mania.—J. W., a colored man, aged forty-eight years, was received into the Georgia State Sanitarium August 2, 1900, with a history of having been violently insane for two weeks. He was a farm laborer by occupation. He had a history of having used alcohol to excess, but no other cause of disease was known. Nothing was known of his family history. His appetite was poor, and sleep irregular. On admission, the patient was in very good physical condition. The temperature was normal, the pulse was slightly accelerated. He remained in a state of very active mania until the time of his death, ten days later. He was constantly incoherent and noisy. Very little nourishment could be given, and that was poorly assimilated. He failed progressively physically, but could not be kept in bed until the day before his death, when he appeared to be quite weak and feeble. There was at no time any febrile action, nor were there any paralyses or localized symptoms pointing to a lesion of the nervous system.

The record of the autopsy made one and one-fourth hours after death shows that upon the right side there was an area of softening, involving the posterior two-thirds of the lenticular nucleus, and the posterior one-half of the caudate nucleus. This condition was present, also, in a number of the projections of the caudate nucleus, extending down between the fibers of the internal capsule. The fibers of the capsule appeared to be normal. The thalami and the remainder of the basal ganglia upon both sides were normal in arrangement and appearance. The blood supply and the consistence of the brain, except in this localized area, were normal. The vessels at the base presented the normal arrangement, but contained a considerable amount of atheromatous changes. Judging from the gross appearance and from a microscopical examination of the softened area, the lesion appeared to be not less than thirty-six to forty-eight hours old.

Case II.—A Case of Terminal Dementia of Four Years' Duration.—E. F., a colored man, aged sixty-two years, had been an inmate of the Sanitarium for two years. During this time his general health had been excellent, requiring no treatment whatever except the ordinary care to be found in an asylum. He was quiet and harmless, his case being a typical one of secondary dementia. On the day of his death he was sitting quietly in the ward, when he suddenly fell from his chair in an attack presenting the following symptoms: The muscles of the entire left side were in a state of chronic contraction. There was marked jerking of both the upper and lower extremities on this side, the muscles of the right side meanwhile remaining quite flaccid. There was complete loss of consciousness. The patient chewed and frothed at the mouth quite like one in an epileptic seizure. This condition continued with remissions and exacerbations for about twenty-five minutes, when the man died.

At the autopsy, one hour after death, the only lesions found which could account for his death were two small hemorrhages in the optic thalamus on the right side, the one being about the size of a pea (5 cm. in diameter), the other about one-fourth as large.

The larger hemorrhage was situated 1.2 cm. from the posterior border, 1 cm. from the superior border of the thalamus, and 0.5 cm. above and internal to the extreme posterior end of the internal capsule. The lesser hemorrhage was on the same level with and about 0.4 cm. anterior to the other. The fibers of the internal capsule did not appear to be pressed upon at all. On microscopical examination the seat of the lesion was found to be in a group of large pigmented cells in the posterior portion of the lateral nucleus of the thalamus.

Case III.—Chronic Mania.—L. M., a colored man, aged thirty-five years, was an epileptic who had been suffering with chronic mania for three years. He had been an inmate of the Sanitarium for one year, in which time he had been under careful observation. During this time he was in a state of constant mania of a rather pronounced type. His general health was good for the greater part of his stay in the institution, and at no time did he present any symptom of localized brain disease. About one month before the date of his death he developed an obstinate enteritis. After this attack he failed rapidly physically, and died apparently from exhaustion.

At the autopsy, four and one-half hours after death, the only gross evidence of brain disease of consequence was a cystic tumor of the pineal gland. The cyst was about four times the size of the normal gland. It had evidently developed within that body, as its attachment to the brain was by means of the peduncles. All trace of the gland had disappeared, except what might be represented by the thin walls of the cyst. The medulla and basal ganglia were preserved in block and hardened in Müller's fluid. From this a series of sections were made at various levels between the lower end of the medulla and the middle commissure, and stained after Pal's modification of the Weigert hæmatoxylin method. A large number of sections from the immediate level of the posterior commissure and pineal glands were studied so that the fiber tracts in this area could be accurately followed.

In this vicinity there are three well-marked tracts of nerve fibers, each of which has by various writers been described as having some connection with the conarium. These are: 1. A bundle of fibers running antero-posteriorly in the angle formed by the superior and internal surfaces of the optic thalamus, and called by various authors peduncles of the pineal gland, pineal stria, tænia thalami, stria medullaris thalami. 2. A small bundle by which the pineal body is attached to the neighboring brain structure, the so-called peduncle of the conarium. 3. A well-marked tract extending downward from the glandula habenulæ, the fasciculus retroflexus (Meynert's bundle).

In this case, none of these tracts presented any evidence of degeneration whatever. In the first of the above-described bundles, namely, the tænia thalami,

there was certainly none to be expected, as it is now a well-established fact that these fibers have their origin in the glanula habenulæ, and have nothing to do with the pineal gland. Gray, however, continues to refer to them as the peduncles of that body. And even so accurate a treatise on anatomy as Quain's says, in describing the peduncles of the conarium, "the upper portion extends on either side along the ridge-like junction of the upper and mesial surfaces of the thalamus as the pineal stria or tænia fornicis."

The second fiber bundle, the so-called peduncle, is described by many authors as springing directly from the pineal body and forming a nerve connection between it and the adjacent parts of the brain. This is plainly an error, for if that were true, the fibers would certainly have degenerated after destruction of the organ from which they originated. Edinger in his "Anatomy of the General Nervous System" in describing the tænia thalami says, "a part of the tænia receiving other fibers on its way passes further backward posterior to the ganglion habenulæ, and then runs to the other side directly in front of the pineal body. The portion between the ganglion and the pineal body is called the pedunculus conarii, because the body appears to rest on it."

Darkschewitsch has described a small bundle of fibers which enters the peduncles of the conarium and crosses to the other side, forming a crossed connection between the optic tract and the nucleus of the oculo-motorius. Thus, according to Edinger, the peduncles of the pineal gland are nothing more than a commissure, and have no real nerve connection with that body. The case in hand would certainly support that view.

Obersteiner in his work on the central nervous system asserts that a part of the peduncles of the pineal body becomes attached to the outer side of the fasciculus retroflexus, and passes downward with it. These we may also take to be commissural fibers, probably either the bundle described by Darkschewitsch or those referred to by Edinger, since there was in this case absolutely no degeneration in the fasciculus retroflexus.

From a study of the above cases the following conclusions may be drawn:

1. The corpus striatum (caudate and lenticular nuclei) has no intimate relation with either the motor or the psychical spheres.

2. There may be a very extensive lesion involving both the caudate and the lenticular nuclei without giving any symptoms.

3. There is in the posterior portion of the lateral nucleus of the optic thalamus an area, irritation of which will produce immediate loss of consciousness with convulsive movements upon the opposite side, and destruction of which will produce immediate death.

4. There may be a tumor of considerable size involving the pineal gland without giving any pressure symptoms.

5. The pineal gland may be entirely destroyed by disease without producing symptoms.

6. There is no tract of nerve fibers originating in the pineal gland and connecting it with the remainder of the brain.

Tropical Ulcer and Its Treatment by Hot Water. Roux speaks of an ulcer common to the natives of the west coast of Madagascar, and its treatment by hot water. It does not often attack Europeans, since their conditions of life are so different from those of the natives. It is found chiefly in the laborers, those subject to wounds and infections. It frequently has its origin in an injury caused by small thorns which are produced by certain kinds of native herbs. These penetrate the skin, and an abscess eventually forms and becomes the seat of various infections. This ulcer is very frequent in its occurrence and shows great resistance to the ordinary remedies. Excellent success has attended the use of hot water of 55° to 60° C. (131° to 140° F.). The water is boiled for fully fifteen minutes, and is then cooled down to about 55° C. The water is applied first by squeezing it out of a pad onto the ulcer, care being taken to protect the neighboring parts. A pad soaked in the water is next applied and allowed to remain some minutes on the ulcer. Next a compress of gauze wet in the hot water is laid on the ulcer previously covered with vaseline; over this a pad of absorbent cotton is fixed by a bandage. The dressing is renewed every day and the limb is kept at rest. The cure is speedy; the suppuration ceases, and cicatrization is rapid. When the cure proceeds more slowly, and the presence of syphilis is suspected, iodide of potassium is administered. Ulcers 7 cm. in diameter have been healed in three or four weeks. The writer states that he has now employed this treatment for two years and has discarded all other methods. It is probable that the hot water acts directly on the microorganisms in the wound, attenuating their virulence, and on the general organism, increasing its resistance to the action of the microbes. As soon as the application is made, the base of the ulcer reddens, showing a reflex vasodilator action very favorable to phagocytosis. The cells themselves are reflexly excited, their vitality is increased, and they multiply.—*Le Caducée.*

Significance of Apex Pneumonia.—Acute lobar pneumonia affecting the apex, says E. F. Cordell, is about one-third as frequent as that affecting the base, and of the two apices, the right is affected about three times as often as the left. Involvement of one apex and the opposite base is very rare, and that of the two apices still rarer. Apex pneumonia is not rare in early life, and the relative involvement of the upper and lower lobe corresponds with that in the adult. The general mortality of the apex and basal forms is about the same. Involvement of one apex and the other base does not appear to be a fatal form of double pneumonia, apart from complications. The mortality of uncomplicated apical disease in the child is almost *nil*. Delirium is not an unfavorable prognostic symptom at any age. Intemperance and hyperpyrexia do not increase the relative mortality at the apex. Pericarditis is a fatal complication and Bright's disease and bronchitis render the prognosis much graver. Delirium is not a more frequent or marked symptom in apex cases in the adult, and seems to occur more often in cases with complications than in the basal form. Intemperance, which is the chief cause of this symptom, does not seem to increase its relative frequency at the apex. There is no positive evidence that delirium is more frequent or prominent in the young with apical pneumonia. Pericarditis is relatively more frequent in apex cases. The same appears to be the case with otitis media. It is evident in the case of icterus, hyperpyrexia, endocarditis, meningitis, pleurisy, diabetes, or empyema. Gangrene is doubtful. There is no reason (other than site) why apex pneumonia in the adult should be more readily overlooked. Phthisis is rare in connection with acute lobar pneumonia, and the apex form involves no tendency to eventuate in it. Cases of apex pneumonia, even in the adult, sometimes assume the mildest symptomatology.—*Maryland Medical Journal.*

Insects as a Living Culture Medium for Infectious Diseases. G. Holub has found that insects of all species afford admirable culture media for the study of infectious organisms. Over one thousand inoculations of the virus of soft chancre were made in insects of different varieties without finding a single insusceptible species. The typical streptobacillus was reproduced in pure culture in all instances, even though the material used generally contained many different species of organisms. The in-

sects usually survived the operation twenty-one days if fed, and if allowed no food died in about two weeks. The inoculation is done with a very sharp sterile needle in the heart or tracheal openings between two thoracic segments as far as possible from the digestive and genital organs. Infected insects copulating with healthy ones transmitted the disease to them, showing that it was carried over the whole body by the blood stream. Experiments with syphilitic virus also gave positive results, and the employment of insects to supplement the very limited number of laboratory animals at our disposal will doubtless lead to the acquisition of much additional information concerning the life history of various organisms and their means of entry into the human system.—*Centralblatt für Bact., Parasit-, und Infektionskrankheiten.*

Visceral Hysteria and Hysterical Hyperpyrexia.—Galletta Vircenzo describes the case of a woman who at the age of fifteen years suffered from the vomiting of blood, at twenty-five years had nephrorrhagia, which subsequently recurred at intervals, and was accompanied by spontaneous ecchymoses, increased flow of blood-tinged saliva, and dysmenorrhœa. No organic condition could be found to account for these symptoms, but as the patient was markedly hysterical, and had the various hysterical stigmata, the author ascribes the condition to hysteria. The patient's father and uncle died of cerebral hemorrhage, an aunt of cerebral thrombosis, and a sister and two nieces suffered from cutaneous hemorrhages. The writer believes that the vascular system of the family was defective, and that the neurosis chose it for its manifestations, as the seat of least resistance. Hyperpyrexia was also present, which the writer believes to have been of hysterical origin. Without the closest attention and the constant recollection of the symptoms that may be due to hysteria, physicians are liable to make a diagnosis of gastric ulcer, pulmonary phthisis, acute peritonitis, hepatic colic, and even appendicitis, to the injury of the patient and of the reputation of the practitioner.—*Giornale Internazionale delle Scienze Mediche.*

Ogata's New Method of Resuscitation.—M. Ogata and J. Futagawa recommend what they call the stroke resuscitation for asphyxia, and the shaking resuscitation for anæsthesia. The former consists of a light stroke over the antero-inferior margin of the chest with the palmar side of the extended fingers, repeated ten to fifteen times a minute. The respiration is stimulated, the heart's action excited, and the circulation accelerated. Shaking resuscitation is performed as follows. The feet of the child are grasped by one hand and the shoulders held by the other; the trunk is gradually raised, and the head brought near the feet, the body being strongly flexed at the hip-joint, while the chest is pressed with the hand. The head is then raised, the trunk gradually extended, and the child returned to its former extended position. Thus expiration and inspiration are secured. Should a repetition of this procedure be fruitless, after a moment's pause in the second posture, the hand on the back is suddenly removed, the upper part of the child's body being thus thrown down and shaken. This should be done eight to ten times a minute, and a warm bath given after each eight or ten shakings. The authors claim that this method of resuscitation surpasses all others.—*The Sei-I-Kwai Medical Journal.*

Chronic Intestinal Obstruction with Report of a Case.—D. S. Hanson says that this affection may be congenital or acquired. The latter form may be due to several causes, mainly inflammatory in character, the most common being adhesive bands; the result of inflammatory exudates not wholly absorbed, and producing obstruction by contraction. Local tuberculous or syphilitic processes may cause obstruction. After reduction of strangulated hernia or of intussusception, there may be obstruction. Rectal obstruction may be due to polypi, hypertrophied valves, and foreign bodies of various kinds. Symptoms present are constipation, eructations, tympanites due to gas in the intestine above the obstruction, diarrhœa, sometimes alternating with constipation, and colicky pains. As obstruction becomes nearly or quite complete, vomiting supervenes, and symptoms develop resembling those due to acute obstruction. It is surprising to note how well a child will do when the caliber of the intestine is reduced to even as low as one-sixth to one-eighth in diameter. In marked cases of long standing, the fluid portion of intestinal contents may be absorbed, causing headache, nervousness, moroseness, foul breath, coated tongue, dry skin, etc., while the child is poorly nourished and easily fatigued. The author reports a fatal case occurring in a boy of seven years.—*Pediatrics.*

Two Cases of Chronic Hydrocephalus in Infants Treated by Tapping and by the Introduction of Aseptic Air in the Place of the Fluid.—William Ewart and W. Lee Dickinson conclude provisionally, from their satisfactory cases, that with due precaution the fluid of chronic hydrocephalus may be completely evacuated from the yet inclosed skull of infants, and aseptic air may be allowed to take its place. This operation may be repeated without detriment, and with scarcely more risk than belongs to the usual method of paracentesis. In favorable cases of moderate effusion, a single operation may suffice. Continued oozing from the puncture for a few days after the removal of the tubes is not unfavorable. In cases of considerable effusion, an obvious indication is to relieve the brain from the weight and from the pressure of the fluid. The evacuation is facilitated by the introduction of aseptic air. By a timely repetition of the operation, a hydrocephalic infant might be enabled to carry the weight of the head, and if the treatment were begun sufficiently early, permanent damage to the brain tissue might be averted, and a normal development might perhaps ensue. Any abrupt movement of the head, eliciting a splashing sound, should be avoided.—*Pediatrics.*

Contribution to the Diagnosis and Treatment of Cholecystalgia from Adhesive Pericholecystitis.—Ferdinando Gangitano describes a case in which operation caused complete relief by breaking down adhesions between the gall-bladder and neighboring organs. The diagnosis between this condition and calculus is difficult, but there is one symptom which the author considers of importance, namely, a sense of continued weight and pulling in the right hypocardium, which is increased after meals. If a patient has attacks of hepatic colic without fever or jaundice, with no increase in size of liver or gall-bladder, and without the presence of calculi in the fæces, and who has previously suffered from diseases which might have produced inflammatory processes in the internal organs, it is reasonable to suspect that the hepatic colic is not due to calculi of the gall-bladder, but to adhesions or structural lesions of its walls. Surgical measures only will afford relief.—*La Riforma Medica.*

Treatment of Gastralgia.—Robert Saundby advises a Weir Mitchell course, change of scene, a sea voyage, or stay in the mountains, with abundant food at regular intervals. Pain can be relieved by heroin. If this is insufficient, the stomach should have complete rest and the patient be fed by enemata—an egg beaten up in four ounces of milk and given every four hours. Pain is often caused by gastroptosis, the palliative treatment for which is to make the patient recline for one hour after meals, to wear a light abdominal belt, and to take immediately after eating a mixture of dilute hydrochloric acid, 15 minims; tincture of nux vomica, 10 minims; liquid extract of cascara, 10 minims; infusion of gentian, enough to make 1 ounce. The amount of cascara may be increased or diminished as required, but these patients are generally constipated.—*Treatment.*

MEDICAL RECORD:

New York, November 2, 1901.

INDUSTRIAL INSURANCE AND THE PREVENTION OF TUBERCULOSIS.

MR. FREDERICK L. HOFFMAN, statistician of the Prudential Insurance Company of America, read at the recent British Congress on Tuberculosis a paper bearing the above title. How closely insurance companies are connected with preventive medicine and sanitary questions need not be discussed, as it is plain to every one that such matters must affect them most intimately. The paper read by Mr. Hoffman exhibits the subject in all its ramifications, and is worthy of a careful study by physicians and others who take interest in the health of the masses. The mortality from consumption is treated from every point of view, age and sex, race, and occupation. The financial importance of the problem is dealt with. The question of diagnosis in all its phases is ably treated, and the very important point as to whether it would be in the interest of industrial insurance companies to contribute toward the erection and maintenance of sanatoria for the treatment of policy-holders suffering from tuberculosis in its early stages is argued at some length. The Government branches of the German insurance system are at the present time trying such an innovation, but Mr. Hoffman asserts that the plan is impossible—that is, with a fair chance of success to private companies. He speaks on the question as follows:

"The Industrial Companies insure millions of policies for small sums, on the average about $150. On the deaths from this cause one company received but $24 in premiums to every $134 paid out in losses. This sum of $24 represents the equity of the policy-holder, but only a portion of this represents the reserve or possible cash surrender value, and hence the amounts actually paid by industrial policy-holders do not possess the necessary intrinsic value to provide for sanatoria treatment at even the most reasonable institution and for the most reasonable period."

Mr. Hoffman reviews the cost and duration of sanatorium treatment, showing that the lowest amount which would provide for such treatment is $65, and holds that, as the average industrial policy-holder will have paid but $24 to the company, it would be absurd to expect companies to undergo such financial loss as these figures imply by supporting sanatoria. He concludes as follows:

"The error which underlies most of the reasoning on this subject by the advocates of insurance assistance is that the amounts of insurance to be paid at death are assumed to have been saved to the company if death from tuberculosis has been avoided by proper treatment. Manifestly, it requires but a moment's thought to make it clear that the financial interest of the companies is limited to the increased duration of policy-life, or the increased premium income in consequence of prolonged existence. I have tried to obtain data on this point, but the fragmentary character of the German experiments has not made it clear to me that the increased longevity is on the average very considerable, from an insurance point of view. Let us assume it to be five years, which I am told is perhaps too high. The company receives five more years of premiums at, say, $7.80 per annum, about $40 in all, or not half enough to meet the average expenses incurred by proper treatment at a sanatorium. The policy-holder must die from some cause and the amount of the policy must be paid some time, hence if increased duration of life is not sufficient to provide, by increased premiums, the cost of treatment, the companies cannot engage in this undertaking."

Mr. Hoffman undoubtedly puts the case for the insurance companies most lucidly, but before passing an opinion on the matter it would perhaps be wise to hear the views of other insurance experts.

DECIDUOMA MALIGNUM.

BEFORE 1888, deciduoma malignum was not recognized as a definite pathological entity, though it was a known fact and had been commented upon by several observers that, after normal delivery, abortion, and particularly vesicular mole, a few patients died of a rapidly fatal disease which showed at autopsy sarcoma-like masses in the uterus, and often extensive metastatic deposits in various parts of the body. In the year just mentioned, Sänger described several cases, recognized the disease as being different from ordinary sarcoma, and named it deciduoma malignum, by which term it is most often known at present. In 1893, he published a further contribution to the subject, and changed his designation to sarcoma deciduo-cellulare, thinking that this more accurately described the histological structure of the growth.

Since Sänger's contributions there have been others; but beyond giving us an accurate clinical picture of the disease and settling some facts as to its frequency and occurrence, not much has been done. The exact nature of the growth is still a subject of controversy.

However, certain facts in this connection have been brought to light, and though not accepted by all, they probably rest on a sound basis. It is practically certain that the neoplasm is of fœtal origin, and that the maternal tissues are only involved by contiguity. That peculiar mass of tissue called the syncytium is apparently the starting point of the disease, and on this account the growth has sometimes been called syncytioma malignum. When this syncytium begins to grow in an atypical manner, it shows a decided tendency to open blood-vessels and to disseminate itself by these channels, in this regard resembling strongly certain characteristic forms of sarcoma, though we are not therefore necessarily justified in classifying the growth as sarcoma. The syncytium has another peculiarity, consisting in the fact that ordinarily it is not divided into cells, though large nuclei can be seen in it. In some instances, however, distinct division into cells can be made out.

It may be said that up to the present the most

accurate classification calls deciduoma malignum an epithelial neoplasm of epiblastic origin, and that it is apparently closely related, certainly in its clinical behavior, to the angiosarcomata or endotheliomata. A fair general idea of the character of this growth may be got by remembering that deciduoma malignum bears the same relation to normal placenta as is borne by carcinoma of the breast to normal mammary gland—that is each of the pathological forms represents the atypical development of a tissue which should pursue a normal course of growth.

To make a diagnosis of this fortunately rare disease is not difficult. The symptoms usually appear within a few weeks of the delivery, abortion, or vesicular mole, and an antecedent history of the last is so frequent in these cases that every instance of it should be observed until danger is past. The chief symptom is persistent hemorrhage, and when it appears no time should be lost in having some scrapings from the interior of the uterus examined by the pathologist, so that if necessary prompt treatment may be undertaken. The course of the disease when not interfered with is one of extreme malignancy and usually lasts only two or three months, when the patient dies from exhaustion and metastases. Up to the present, no treatment holds out the least prospect of permanent benefit; but immediate hysterectomy, done by whatever method, insures the most complete removal of the local disease. After the disease has once extended beyond the uterine cavity, no treatment is of the least avail. That even in the presence of this very malignant condition we are not helpless if we act promptly may be gathered from some statistics collected by R. Williams. Out of fourteen cases operated on by hysterectomy, twelve survived the immediate operation, and of these, five were known to have died within a year. Of the remainder, six were known to be living at periods of from three to ten months, and also to be free from recurrence. This showing is not so bad when the extreme malignancy of the disease is remembered, and future improvement may be looked for in the direction of early diagnosis, and consequent promptness of treatment. The disease is happily rare; but cases appear from time to time, and when they do, they should be studied carefully, especially in their pathology and histology.

THE ARMY MEDICAL SCHOOL.

The session of the Army Medical School for 1901–2 will commence on November 1 in the lecture rooms and laboratories of the school at the Army Medical Museum, Washington, D. C., continuing for five months. The operation of this School, established in 1893 by Surgeon-General Sternberg, has been suspended since 1897, owing to the pressing necessity for the services of medical officers in the field during the war with Spain and, subsequently, during the active hostilities in the Philippines. The course of instruction is planned so to supplement the ordinary medical school curriculum as specially to fit young army surgeons for the specialized duties of medical officers, and to enable them to acquire in a few months, by systematized instruction, a competent knowledge of medico-military matters which would otherwise only be obtained by long, actual experience with military conditions—in the latter case probably to the detriment of the service, and the occasional mortification of the young medical officer, as a result of mistakes depending on inexperience. The faculty of the school is composed of older medical officers of the army stationed in Washington, and assigned to duty in the various departments of instruction by reason of their particular fitness for such duties, special courses of lectures also being given by various experts of the Department of Agriculture and other branches of the general Government at Washington. The curriculum includes instruction in military medicine and surgery; general and military hygiene; the relations, duties, and status of the army medical officer; bacteriology, pathology, and sanitary chemistry; hospital-corps drill; preparation of army papers; international law; animal parasites, etc. The large number of untrained medical men who have lately entered the army has made it necessary to increase the capacity of the school and the size of the classes, and considerable enlargement of the laboratory facilities has been rendered necessary. There has been some delay in the accomplishment of the latter, owing to the question as to the proper appropriation from which the necessary funds could be drawn for this purpose; but the matter has been finally settled, and the course at the school will be begun promptly at the usual time. Nineteen young medical officers have already been ordered to Washington for instruction, besides which a number of medical officers stationed at posts near or at that city will be expected to secure such benefit from the courses at the school as their official duties will permit. With the mistakes made by untrained medical officers from civil life, who hastily donned an army uniform during the war with Spain, fresh in the recollection, the immense value to the country, military service, and individual, of such instruction as will be given at the Army Medical School, will be fully appreciated. To the foresight, energy, and ability of Surgeon-General Sternberg, the establishment and maintenance of this most valuable educational medico-military institution will remain a lasting monument long after he shall have relinquished the responsibilities of his present position for a well-earned rest upon the retired list.

Treatment of Certain Purulent Conditions of the Antrum of Highmore Through the Natural Openings.—Norval H. Pierce maintains that there is strong evidence to warrant the belief that in diseased antra accessory openings are more frequently found than in healthy antra; that in a certain number of cases the ostium may be used to irrigate the antrum; that we should in all cases, whether for diagnosis or treatment, try for the ostium or accessory openings before resorting to surgical puncture, whether through the inferior or middle meatus, the canine fossa, or alveolar process; that it is of no importance whether the opening through which we irrigate be the ostium or an accessory opening.—*The Laryngoscope.*

Hysteria in a Girl of Twelve Years.—René Cruchet reports a case in which there was complete left hemianæsthesia, nine crises of double amaurosis, and perversion of binocular vision, all shown to have been of hysterical origin. The patient was not consciously or willingly hysterical, but the attacks of blindness, etc. appeared to come on after slight mental disturbance or disappointment, and sometimes with no apparent cause. The onset of the hysteria coincided with the first menstrual period; the second menstrual period occurred nine months later, just before the eighth attack of blindness. Whether there was any relation of cause and effect here, the author was unable to say.—*Archives de Neurologie.*

News of the Week.

The Pan-American Emergency Hospital will be formally closed on Saturday, November 2, after having treated more than 6,000 patients, thus ending the usefulness of the most beneficent and admirably managed institution connected with the administration and operation of the Exposition. Under the management of Dr. Roswell Park, the medical director; his assistant, Dr. Veitner Kenerson, and Dr. Nelson Wilson, the sanitary officer, together with the staff of resident physicians and nurses, the institution has made a splendid professional and humanitarian record. The crowds that frequented the Exposition, as well as the employees, found it a Samaritan retreat where relief was always forthcoming for the sick or injured. Its reception of President McKinley, together with the admirable facilities which it afforded for the necessary operation after his shooting by the assassin, Czolgosz, alone was ample repayment for the expense of maintenance.

To meet the needs of such emergency cases as may arise in the future during the breaking up of the Exposition and the demolition of its buildings, a small hospital will be established and maintained in the Service Building for the period of three months, in charge of Dr. Zittel, a member of the present house staff. For the admirable operation and results of the Emergency Hospital, too much praise cannot be given to Dr. Park, whose unremitting labors, to make this institution the success it has proved to be, have been a severe tax upon his energies during a most trying period.

The Exhibit of the Medical Department of the Navy at the Pan-American Exposition will be transferred in its entirety to the coming Exposition at Charleston, S. C., as will also the exhibit of the Marine Hospital Service. The very popular field-hospital exhibit of the Medical Department of the Army has been applied for by the Charleston Exposition authorities, but as yet no definite action has been taken on their request. It is possible that the exhibit relating to public health will be included in the exhibit relating to liberal arts now being made up for shipment to Charleston.

The Hackensack Hospital, N. J.—On Saturday, October 26, the new building of the Hackensack Hospital was opened to the inspection of the public. The present structure, complete in all its details of arrangement of wards, operating room, private apartments, and sanitary equipment, was made possible by the indefatigable exertions of Dr. David St. John and the many influential friends of his town. The capacity of the institution is seventy-five beds. Besides a large consulting staff of New York physicians and surgeons, it has a flourishing training school for nurses.

Navy Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the Medical Corps of the Navy, week ending October 26, 1901: October 21.—Surgeon J. M. Edgar, ordered to the *Wabash*, October 23, as relief of Surgeon H. G. Beyer. Surgeon H. G. Beyer, detached from the *Wabash*, upon reporting of relief, and ordered to the *Prairie* when put into commission. Asst. Surgeon R. T. Atkinson, detached from the *Wabash*, October 30, and ordered to the *Prairie* when put into commission. Asst. Surgeon D. B. Kerr, ordered to the *Wabash*, October 28. Asst. Surgeon E. Thompson, ordered to the Naval Hospital, Boston, Mass., October 26. October 22.—Surgeon G. Pickrell, detached from the *Columbia*, upon reporting of relief, and ordered to the Naval Dispensary, Washington, D. C. Surgeon P. Leach, ordered to the *Columbia*, as relief of Surgeon G. Pickrell. Passed Asst. Surgeon R. M. Kennedy, ordered to the *Franklin*. Assist. Surgeon A. G. Grunwell, ordered to the Naval Hospital, Norfolk, Va., November 1. Asst. Surgeon L. W. Bishop, ordered to the *Independence*. October 24.—Pharmacist H. Henry, detached from the *Independence* and ordered to the Bureau of Medicine and Surgery, Navy Department.

Dinner to Professor Waldeyer.—The German Medical Society of the City of New York celebrated the presence of Professor Waldeyer in the United States by a dinner at Delmonico's on Saturday, October 26. Dr. Geo. W. Jacoby, the President of the society, welcomed the guest in a masterly address in German, and presented to the distinguished foreigner a diploma of honorary membership to the society. Addresses were also made by Drs. A. Jacobi, Wm. H. Welch of Baltimore, and Carl Beck. To these Professor Waldeyer feelingly responded, paying many graceful compliments to American medicine. One of the reasons for Professor Waldeyer's visit to this country was to accept the distinguished honor of a degree of LL.D. from Yale University on the occasion of the bi-centennial of that institution.

A Story by Telegraph.—From the Washington *News Letter Leaflet*, a Christian Science publication apparently devoted to the exploitation of the remarkable healing abilities of its editor, we clip the following:

EARLHAM, N. Mex., August 11, 1901.

O. C. SABIN,

1800 Belmont ave., Washington, D. C.

Treat son Earnest for fever.

(Signed) ——— ———

EARLHAM, N. Mex., August 13, 1901.

O. C. SABIN,

1800 Wyoming ave., Washington, D. C.

Fever yet; some better; treat parents for fear.

(Signed) ——— ———

EARLHAM, N. Mex., August 15, 1901.

O. C. SABIN,

1800 Belmont ave., Washington, D. C.

Earnest well; stop treatment.

(Signed) ——— ———

The use of identical methods for the alleviation of both fever and fear—and presumably fractures would receive the same "treatment"—illustrates the therapeutic possibilities of Christian Science as accepted by the deluded minds of the followers of that cult.

Yale University Bi-Centennial Celebration.—At the recent bi-centennial celebration of Yale University, the oration in the department of medicine was delivered by Prof. Wm. H. Welch of Johns Hopkins University. Subsequently, the degree of LL.D. was conferred upon Dr. Welch and also upon Dr. J. S. Billings, U. S. Army, now librarian of the New York consolidated libraries.

Meeting of Health Officials.—The first annual convocation of health officials of the various cities, towns, and villages of New York State was held last week in Albany, on the invitation of Dr. Daniel Lewis of this city, the State Commissioner of Health.

The Rockefeller Institute for Medical Research.—The officers of this institute have adopted a tentative working plan. They will expend $20,000 a year, divided so as to provide for forty annual scholarships. Candidates for these scholarships must be recommended by the heads of various laboratories to the board of directors, and must agree to pursue investigations in some important subject of pathology, bacteriology, or hygiene.

A Gift from Philadelphia to New York—Wung Ta Sung, a Chinese laundry worker, at 6001 West-

minster Avenue, has what is pronounced to be a true case of leprosy. He presents a number of large skin lesions on his shoulders and back. The fact that the patient has been occupied daily in washing other people's clothing makes the discovery of the dread disease somewhat sensational, though there is little or no danger that any spread of the disease could be started in this way. (He left for New York before the Municipal Hospital physician had located him.)—*Philadelphia Medical Journal.*

The Health of King Edward.—Various rumors are again current regarding the health of the King of England. A London weekly publication, on Saturday last, asserted that since his Majesty's accession three operations have been performed for the removal of papilloma on the left vocal chord, and that one was removed from the right vocal chord last week. "Assistance was hastily summoned," says this journal, "as his Majesty was breathing with difficulty, and an immediate operation was performed. But it was regarded as a only temporary relief, the injured epithelium now having become a cancerous growth, and serious developments are expected." We can only hope that this rumor is as unfounded as most of the reports started from time to time regarding the various rulers of European states, but the persistence and the circumstantiality of these reports concerning the King are at least disquieting.

Havana's Excellent Health Conditions.—The reports issued monthly by Major W. C. Gorgas, Chief Sanitary Officer, on the health conditions in Havana, are growing to be very monotonous with their unvarying statements of lessening mortality. In the report of vital statistics for September we find that there were but 339 deaths, a death rate of 15.64 per thousand. This is the best showing ever made for any month in Havana, and when we compare it with the death rate of any northern city of the same size (260,000 inhabitants), remembering that Havana is unsewered and the streets are paved with Belgian blocks and cobblestones, and not with asphalt, it is little short of marvelous. There were only two deaths from yellow fever in the city during the month. In September, 1896, there were 166 deaths from this cause. From April 1 to October 1 of this year, yellow fever caused only five deaths in Havana, as compared with 659 in the corresponding period of 1897, and an average of 296 deaths for the past eleven years. As accounting for the great improvement in the condition of the public health, Major Gorgas says: "This year, since the 1st of March, we have had one hundred men daily engaged in killing mosquitos in every way we know how. The result is that, instead of having fifty-two deaths from yellow fever and thirty-two from malarial fever, we have had two deaths from yellow fever and eleven from malarial fever—a difference of seventy-one deaths, under those two heads, in favor of this year. Again, last year, during September, there were seventy-two deaths from tuberculosis; this year, fifty-eight. This, it is thought, is in great part due to the special efforts made in this direction, the system in vogue in New York having been put into effect here. A record is kept of all tuberculosis in the city, and disinfectants and literature on the subject of tuberculosis are freely supplied to those suffering from this disease, through their physicians. In comparing September, 1900, with September, 1901, we find that these three diseases—yellow fever, malarial fever, and tuberculosis—have been most marked in their decrease. But, not considering these three diseases, there has been a general decrease in the death rate. This, it is thought, is due to an improvement in the general sanitation, but more particularly to improvement in the interior hygiene of the houses. The constant house-to-house inspection has enabled this department to force the people to keep the interior of the houses in good condition. They have made great improvements in this respect since last September." Of other infectious diseases there were scarcely any cases. There were but seven deaths from typhoid fever and three from diphtheria during the month. No scarlet fever exists in the city, and there has been no smallpox there for over a year. If we were not in the midst of a political campaign, and so in danger of having our remarks misconstrued, we might make some comment on the relation of clean streets to the health of a city, so we will simply quote what Major Gorgas says: "The streets have been kept in excellent condition by the engineer department. I know of no city where they are cleaner, nor where the garbage is better collected. It is exceedingly rare in Havana to see an unemptied garbage can on the street after daylight." The evidence of the complicity of the mosquito in the spread of yellow fever, presented by these reports, becomes stronger each month. "As to yellow fever," Major Gorgas writes, "there has never been an approximation to this condition at any time in the last one hundred and fifty years. This is the first year, during that period, in which we have known that yellow fever was conveyed by the mosquito; and during February the Military Governor directed that our disinfection be carried out on these lines. I attribute our very surprising results to this fact. As each month passes, we feel more and more confident that the problem of the control of yellow fever has been solved by the discovery that the mosquito is its conveyor; and little anxiety is now felt when a focus develops in the city. From repeated successes in the last six months, we believe that, with present disinfection methods, any infection from yellow fever that may be introduced into the city can be stamped out."

The Virchow Celebration. — The issue of the *Berliner klinische Wochenschrift* for October 14 is devoted to the celebration of Professor Rudolf Virchow's eightieth birthday, appreciative articles being written by many men of many lands. Baccelli opens with a greeting in Latin, Cornil writes in French, and Pye-Smith in English; the other articles are in German. Stokirs writes on the influence of Virchow on Dutch medicine, Scharvinsky on Russian, Sundberg on Swedish, Salomonsen on Danish, Karamitzas on Greek, Jacobi on American, and Weichsenbaum and Zuckerkandl on Austrian. Israel contributes a descriptive article on the Pathological Museum at the Friedrich Wilhelms University in Berlin.

A Nurses' Home for St. Vincent's Hospital.—An appeal has been made by the Sisters of Charity and Ladies' Auxiliary of this hospital for donations to enable them to build a home for the nurses in the hospital training school. At present the quarters for the students in the training school are very inadequate.

The Southern Homœopathic Medical Association in session last week at Atlanta, Ga., elected Dr. Susan M. Hicks of Atlanta as President. Dr. Hicks has been Second Vice-President of the association during the past year, and was chairman of the local reception committee.

Dr. Rixey's Report on the President's Case.—Dr. Presley M. Rixey, Medical Inspector, U. S. N., has filed with the Surgeon-General of the Navy his official report upon the wounding, illness, and death of the late President McKinley. He gives the cause

of death as follows: "Gangrene of both walls of stomach and pancreas following gunshot wound." Dr. Rixey's report goes into the minutest details of the patient's illness. It shows what the President's condition was from hour to hour—sometimes almost from moment to moment—beginning with the operation in the Exposition Emergency Hospital an hour after the shooting, and ending with the last unavailing efforts to keep the heart beating. The report throws no new light on the medical aspects of the case other than that contained in the official account published two weeks ago, but it shows at times a curious discrepancy between the optimism of the official bulletins and the actual condition of the President at the time.

The Craig Colony Prize.—Under this name a prize of $200 has been offered by Dr. Frederick Peterson of this city for the best original essay on the pathology and treatment of epilepsy. The prize is open to universal competition, but the essay must be written in English. The work must be original, and must not have been published. Each essay must be accompanied by a sealed envelope containing the name and address of the author, and bearing upon the outside a motto or device, which is to be inscribed also upon the essay. All papers received will be submitted to a committee consisting of three members of the New York Neurological Society, and the award will be made upon its recommendation at the annual meeting of the board of managers of the Craig Colony, October 14, 1902. Manuscripts should be sent to Dr. Frederick Peterson, 4 West Fiftieth Street, New York City, on or before September 30, 1902. The successful essay becomes the property of the Craig Colony, and will be published in its medical reports.

The Nicholas Senn Prize.—A gold medal is offered annually by Dr. N. Senn of Chicago for the best essay on some surgical subject written by a member of the American Medical Association. The award will be made under the following conditions: *(a)* The name of the author of each competing essay shall be enclosed in a sealed envelope bearing a suitable motto or device, the essay itself bearing the same motto or device. The title of the successful essay and the motto or device is to be read at the meeting at which the award is made, and the corresponding envelope to be then and there opened and the name of the successful author announced. *(b)* All successful essays become the property of the association. *(c)* The medal shall be conferred and honorable mention made of the two other essays considered worthy of this distinction at a general meeting of the association. *(d)* The competition is to be confined to those who, at the time of entering the competition, as well as at the time of conferring the medal, shall be members of the American Medical Association. *(e)* The competition for the medal will be closed three months before the next annual meeting of the American Medical Association, and no essays will be received after March 1, 1902. Communications may be addressed to any member of the committee, consisting of the following: Dr. Herbert L. Burrell, 22 Newbury Street, Boston, Mass.; Dr. Edward Martin, 415 South Fifteenth Street, Philadelphia, Pa.; Dr. Charles H. Mayo, Rochester, Minn.

The New York City Consumption Hospital. The buildings on Blackwell's Island now used in connection with the Manhattan State Hospital, in which are quartered 850 insane patients, will soon be turned over to New York City by the State Commission in Lunacy. It is reported that these buildings will be used for the proposed New York City Hospital for Consumptives.

Anti-Preservative Law Upheld.—The anti-preservative law passed by the last legislature has been declared constitutional by the Supreme Court of this State. The case came up in Rochester, where adulterated cream was sold, a preservative having been used. Some weeks ago, in the case of a New York City violation, a court declared the law to be unconstitutional.

Smallpox in Alaska.—Captain Tuttle of the revenue cutter *Bear*, recently returned from Behring Sea, reports that at all stations in Alaska visited by him he found the natives had suffered fearful loss from the effect of last year's epidemic of smallpox. Not more than half survived.

The State Colony for the Insane at Islip.—The State Commission in Lunacy has begun the work of transferring the insane patients to the colony connected with the Manhattan State Hospital at Central Islip, L. I. Accommodations are to be provided within the next few months for 2,500 patients, the first to be transferred will be the patients on Blackwell's Island, in order that this property may be returned to the city under the terms of the original act transferring the insane of New York City to the State. Relief will also be granted to the other New York City asylums, and in addition the commission will transfer New York patients now in the Poughkeepsie and Buffalo State hospitals to the new colony buildings.

The American Academy of Medicine.—At the meeting of the American Academy of Medicine in Atlantic City, in 1900, Dr. E. F. Wilson of Columbus, Ohio, made the suggestion that the Fellows of the Academy hold informal meetings in various parts of the country. Many of the members do not find it convenient to attend the general meetings of the academy, and it was thought that these local meetings would be enjoyable to those participating, and helpful to the objects for which the academy exists. Acting upon this suggestion, a meeting was held in Philadelphia last winter, which was both enjoyable and profitable. At the meeting of the academy in St. Paul, last June, the plan was commended, and arrangements were perfected by which these local meetings could be special meetings of the academy with power to elect members and transact other business subject to the approval of the annual session. A project is now on foot for holding a special meeting in New York City some time during the coming winter.

The Plague.—It is officially reported that the plague is at an end in Naples. There were but fifteen cases in all, and the time from the discovery of the first case to the discharge of the last from the hospital was but three weeks. In Egypt there were one hundred and sixty cases during a period of six months, only one of these being in the person of a European. In Rio de Janeiro and Campos, Brazil, the epidemic continues, two or three new cases being reported daily. The representative of the United States Marine Hospital Service at Constantinople has made a report on the plague in that city, which he says has been prevalent since last April. He reports that twenty cases have occurred, although the local authorities, following the example of the Sultan, have shown much willingness in taking necessary preventive steps. The disease has been of a mild type as compared with the epidemic in China and India.

General Miles on the Army Canteen.—In the annual report of Lieutenant-General Miles, made public this week, occurs the following paragraph regarding the canteen system, the re-establishment of which he opposes: "Much has been said con-

cerning the army canteen, which, when first established, was called the 'amusement room,' and afterward the 'post exchange.' It was a place of amusement and recreation for the enlisted men, where they could enjoy reading books and papers, playing games, etc., and could purchase such refreshments, except liquors, as they desired. It was then an eminently successful institution, and promoted the contentment and general welfare of the troops. Later, when what was known as the post traders' establishments were abolished, light wines and beers were authorized to be sold in the canteen. The Government has now, by act of Congress, prohibited the sale of intoxicating beverages in the canteen, and it is believed that no injury has resulted thereby, and that the law has, in the main, been beneficial."

Obituary Notes.—Dr. MELVILLE D. PECK, for many years chief clerk of the Patent Office, and afterward a practising patent attorney in Washington, died at his home in that city yesterday, in his sixtieth year. He was born in Solon, N. Y., served in the Tenth New York Cavalry during the Civil War, and at its close studied medicine, obtaining his degree from the medical department of Columbia University, Washington, in 1869. He practised medicine at Cortland, N. Y., for a time, and later was appointed to the Pension Bureau, and in 1875 was transferred to the Patent Office as an examiner, and soon promoted to the chief clerkship.

Dr. LEONARD LATTER of Monument Beach, Mass., one of the most widely known physicians of the Cape Cod district, died at his home, last week, at the age of fifty years. He was born in England, but was graduated in medicine from the Detroit Medical College in the class of 1875.

Dr. MORITZ C. HERRMANN died at his home in this city on October 24, at the age of eighty-eight years.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

COMMITTEES ON MEDICAL AND NURSING SERVICES—SMALLPOX — SOCIETIES — TUBERCULOSIS — TROPICAL EXPEDITIONS—BIRMINGHAM INSTITUTE—DR. YELLOWLEES—NATIONAL HOSPITAL.

LONDON, Oct 11, 1901.

THE report of the committee on the reorganization of the army medical service does not impress one more favorably on further consideration. There was quite a chorus of praise in the general newspapers on its issue, and at first sight there is an appearance of an attempt to render the service more attractive. From a recruiting point of view, this is right enough, but it will be useless to bring young men into the service unless the conditions are made such that they will be likely to remain a reasonable time. There is an effort to attract some of the best men by a concession to those who pass the entrance examination while holding a resident hospital appointment. But it is not sufficient to attract such men. They must be retained—not driven to leave the service at the first opportunity. To this end the combatant branches must be given to understand that their supercilious insolence must cease. Incompetence among military officers has been so conspicuous in the present war that they should take home the lesson afforded by the example of the doctors that it is necessary to learn their profession. We might then cease to hear of infantry impeded with furniture trying to catch well-mounted flying men.

The report recommends a great change in the entrance examination, so that candidates need not go back to grind up elementary subjects, but will only be called upon to display adequate knowledge of medicine and surgery. But afterward, at each step, he will have to pass an examination to be eligible for promotion, until he reaches the rank of lieutenant-colonel. It is true that study-leave is proposed, but even with this it is not every candidate who will relish the possibility that a slip in an examination will arrest his promotion. Moreover, the most successful men at the examining board do not necessarily prove superior in practice. Every teacher can give you examples of this.

The report does not provide for an increase in the medical staff. It recommends that a scheme should be prepared to provide for an expansion of the service in the time of war or of epidemics. But first of all it should have insisted on the service being raised to a proper standard on its peace footing. The service is undermanned now, as I have told you several times. The committee ignores this, and yet it is the most important fact. If the civilian members allowed themselves to be hoodwinked on this point, they have lost a great opportunity of rendering good service to their country. I fear this may be so, and I am inclined to think the civilian element was too largely represented on the committee. This misgiving is intensified by a glance at the constitution of the "Advisory Board," which is to be set up, and which is, in fact, the basis of the whole scheme. This advisory board is to consist of the director-general and his deputy, two officers of the R. A. M. C., one with special knowledge of sanitation and the other of tropical diseases; two civilian surgeons and two civilian physicians; a representative of the war office and another of the India office, and the matron-in-chief (!) of the Queen's Imperial Military Nursing Service.

Thus, there is to be set up a board dominated by civilians, and the R. A. M. C. is to be under "the supervision" of that board, whatever that may mean. One would have supposed that army surgeons, with their splendid record of scientific work and active service, might have managed to form an advisory board, without the help of civilian physicians and surgeons and a matron. Male nurses might more appropriately be trusted to advise on army nursing, but the women whose delicacy makes them cry out for female doctors are first to push women forward as nurses for men.

After all, the report of the committee is only a recommendation to set up another board with powers about as limited as its own. For the advisory board's "supervision" will be itself supervised by the war office. Its advice may be accepted or rejected by the war minister. To have any authority, it will have to be embodied in a royal warrant, and history tells of even royal warrants being set at naught by war office intrigues and our "military advisers."

The committee on the reorganization of army nursing was composed of the same persons as that on the medical service, and their report naturally follows on somewhat similar lines. They recommend that there shall be one nursing service for "the army in the United Kingdom, India, and the Colonies, to be designated Queen Alexandra's Imperial Military Nursing Service (Q. A. I. M. N. S.)." What a clumsy designation, either in full or the initials kindly supplied! The director-general is to be chairman of the nursing board, on which two members of the advisory board of the army medical service are to sit, one of whom must be a civilian. Two members are to be appointed by the Queen (as president), and one by the India office. The matron-in-chief of the Q. A. I. M. N. S. and three matrons of civil hospitals complete the proposed board. This looks as if everything is to be handed over to women and civilians, thus pushing the notion that nurses are independent of doctors instead of being their servants, and that only women are the proper persons to nurse soldiers whatever may be the matter with them. This is what comes of appointing a committee in which the civilian element is in the ascendant to inquire into military matters. Even the civil surgeons who served for a few weeks in the South-African war cannot bring to a committee the experience of army surgeons of high rank and long service. It might have been thought, too, that, having experienced "the plague of women," they would not have proposed to hand over to them all nursing authority. The army possesses a body of male nurses with a better training for their work than any civilian matrons or civil hospital nurses, and as soldiers are men, it is easy to see how often men should be their nurses.

Smallpox has continued its invasion at about the same pace during the week, and the London School Board has continued its obstruction at the instigation of faddists.

The obstetrical and the West London societies have held meetings, and next week several others will begin their work.

The local government board for Ireland has circularized the various bodies under its control on the subject of tuberculosis, pointing out the influence of overcrowding, want of ventilation, and general sanitary defects in predisposing to the disease, the agency of the operations in conveying contagion, and the value of sanatoria. The board has also issued a leaflet giving "information for consumptive people and those who live with them." This states that consumption is curable and preventable, and

gives advice as to the precautions that should be taken. These are such as many medical officers of health have enjoined. Perhaps their official recommendation may give them more authority with the public.

The Prisons Commissioners have just issued their report for the year ending March 31 last. It shows a steady decrease in crime throughout the country. The commissioners reiterate their opinion that the repression of crime can best be accomplished by concentrating attention and care on the young, as they are by far the most amenable to good influences. The statistics in this report support their view.

The health of prisoners is carefully considered, and the mortality is low—about half what it was twenty years ago.

Sir F. Lovell, late surgeon-general of Trinidad, has undertaken a mission on behalf of the London School of Tropical Medicine.

Another expedition is going to Christmas Island to investigate beriberi. Mr. H. E. Durham is the leader, and a son of Dr. P. Manson will join him.

Exit the Birmingham Consultative Institution. For once the profession has prevailed against a determined attempt to injure it. The plate has now been removed from the door of its habitat, and it will soon be forgotten.

Dr. Yellowlees has resigned the physiciancy to Gartnavel asylum for the Insane—the important institution in the west of Scotland, which he has superintended so well for twenty-seven years. He has been made honorary consulting physician in recognition of his valuable services.

The demonstrations at the National Hospital for the paralyzed and epileptic have now been resumed.

THE "NORDISKT MEDICINSKT ARKIV."

To the Editor of the Medical Record

Sir: In your issue of the 12th inst., page 579, there is a statement which reads as follows: "The *Nordiskt Medicinskt Arkiv*, a Norwegian medical quarterly, has abandoned the use of Norwegian, the original contributions being now published in English, French, or German," etc. Now, the fact is that the above-mentioned periodical is and always has been a *Swedish* medical journal, published at Stockholm, under the editorial management of Dr. Axel Key, professor in the Royal Carolean Medical Institute. This journal is, however, the central organ for medical science in the four countries of the North of Europe—Sweden, Norway, Denmark, and Finland—and as such has received contributions in both Swedish and Danish-Norwegian, generally with a brief résumé in French. According to the changed programme, original contributions in English, French, or German are now preferred. Original articles in Swedish or Danish-Norwegian must hereafter be accompanied by a résumé in either of the three languages mentioned. Reviews of Swedish, Norwegian, Danish, and Finnish medical literature will be written in German by the editorial staff translator. From the beginning of this year the journal is issued in two parts quarterly, as you correctly state, one devoted surgical subjects, under the subeditorship of Dr. John rg, the other to medical subjects under the subeditorship of Dr. C. G. Santesson.

In this connection, permit me to call attention to a mistake made some time ago by several of our esteemed medical contemporaries, among them two right here in this city, while mentioning the awarding of the Nobel scientific prizes, which, by the way, according to the rules and regulations of the Nobel Institute, will not be awarded until November next. With the exception of the Medical Record and the *Journal of the Am. Med. Ass'n*, they all represented as a Dane the well-known Swedish inventor and manufacturer of explosives, Alfred Nobel, who donated the bulk of his large fortune, which at the beginning of this year amounted to the considerable sum of 31,225,000 kroner ($8,430,000), for the advancement of science and the peace movement all over the world without distinction of nationality or creed. *Suum cuique.*

THE ROCKEFELLER INSTITUTE.

To the Editor of the Medical Record

Sir: The Milk Commission of the Medical Society of the County of New York regret that in the report recently published, a wrong impression was inadvertently conveyed which, in justice to workers of the Rockefeller Institute and to themselves, they would like to correct. The Milk Commission has interested the dealers and the medical profession in certified pure milk, and in the furtherance of its aims has been permitted to use certain data gathered by special workers of the Rockefeller Institute in pursuit of an independent investigation of wider scope which the Institute has undertaken. The data gathered for the Institute which the Milk Commission especially made use of in the above-mentioned report were, in part, bacteriological; while the results of farm investigations and the observations indicating the co-relation of improved sanitary conditions of the dairies, with improvement in the character of the milk, were derived almost wholly from an investigation as yet unfinished, which is being carried on by Dr. Belcher, under the auspices of the Rockefeller Institute.

A Unique Case of Chlorosis. — William Edgar Darnall reports the case of a woman of twenty-two years suffering from chlorosis and chronic constipation. The peculiarity of the case consisted in the temperature curve. It was at 101.4° when the patient was admitted, fell as soon as the bowels were opened, rose steadily to 103°, and fell again when another evacuation took place. This was followed by a rise to 104°, following a day of inactivity. On the seventh day the normal point was reached after a movement from the bowels, but the temperature jumped to 105.2° again after another day without a movement. The bowels then moving every day, the temperature came down and remained normal. Sir Andrew Clarke, followed by Forchheimer, held that prolonged constipation plays an important part in the etiology of chlorosis, the result of constipation being a copræmia, due to the absorption of poisons—leukomains and ptomains—from the larger bowel. The case reported seems to accord with this view.

Tuberculous Peritonitis.—Henri J. Fontaine would give the medical treatment a thorough trial before resorting to laparotomy; the statistics of medical cures being almost as good as those of the surgical, and because, in case of failure, surgery can always be resorted to. Byford would make the supporting treatment subservient to that of the inflammation. He would give salines to produce two or three liquid stools daily; eight or ten grains of salol, guaiacol, or an equivalent, three or four times daily, to aid in disinfecting the alimentary canal, and possibly producing some effect on the bacilli. The diet should be largely liquid, and such as to produce a minimum of gas or solid residuum. As to mercurials, the internal administration of calomel or blue mass is better than inunction, because these preparations stimulate the action of the liver and aid in disinfecting the alimentary canal. The same rest in bed as after abdominal section should be insisted upon. No opium is to be given, except to check diarrhœa, when present. Hot fomentations or the ice bag will relieve pain; acute cases should be treated like cases of ordinary acute peritonitis. The tonic of fresh pure air should never be forgotten in tuberculous cases.

New York Medical Journal, October 26, 1901.

Social Aspects of Dermatology.—The seventh Lane Lecture by Malcolm Morris is devoted to the consideration of syphilis and leprosy. He believes the latter disease to be contagious and says that if leprosy, which has recently become more common, is to be stamped out again, segregation is necessary.

Costume Deformities.—By comparing photographs of the human figure taken by travelers in countries where little or no clothing is worn with the average human figure of to-day, E. H. Bradford draws certain conclusions concerning the modifications produced by the clothing of this later time. The present method of supporting the stockings exerts a strong pull on the waist, borne in the case of women with full hips by the pelvis, but in children mainly on the thorax, and is at times too great a strain on the growing muscles. The injury to the full shape of the neck, which comes from clothing, is seen in the long thin neck with weak muscles and slight subcutaneous adipose tissue, which results from the binding of the neck by collars, stocks, and neck-bands. Among savage women, heavy neck ornaments have a similar effect, weakening and checking the normal development of the trapezii and the sternomastoid muscles, and, by limiting the normal fatty tissue, often making the clavicles unduly prominent. This defect is so frequently reproduced in art that it might be looked upon as a type to be admired, were it not that it is clearly the result of a lack of normal development. The injurious effect of clothing upon the shoulders is seen when the full de-

velopment of the muscles is prevented, and the shoulders are pulled forward, producing the common round-shoulder deformity. Naturally, the effect on the trunk is most noticeable from the effects of corsets. This effect has become so common as to lead to false standards in art as to what is the correct figure. To remove the faults which have gradually introduced themselves, it is necessary to determine normal standards, and to make such standards known. The standard furnished by Greek art might be accepted as a model, but, lest it be discarded as antique, its reliability should be reinforced through examination of figures uninjured by clothing, hard labor, or suffering. From investigation it appears that exaggerated fulness of the hip, disproportional leanness of the legs and lower thighs, the flattened chest, the narrow waist, and the long neck are costume deformities to be avoided in a healthy civilization which seeks to preserve what Nature gives.

Journal of the American Medical Association, Oct. 26, 1901.

A Case of Tetanus; Use of Antitetanus Serum; Death.—The patient of T. G. Scott was a woman of twenty-one years, who had stepped on a nail. Symptoms of tetanus appeared on the fifth day, and were severe twenty-four hours later. An area of tissue about the wound was removed, and antitetanus serum was injected. There was little or no temporary improvement, and death ensued inside of forty-eight hours.

The Psychoses of Cerebral Syphilis.—R. Dewey has analyzed over twelve hundred cases of all forms of nervous and mental diseases, finding forty-five due to well-substantiated cases of constitutional syphilis. They were made up as follows: 17 were diagnosed as paresis; 12 as syphilitic brain disease with symptoms of organic lesion; 7 were cases of psychoses with marked delusional characteristics and without symptoms of brain syphilis, the mental symptoms taking the form of delirium, stupor, extremes of exaltation and depression, aphasic attacks, and mild dementia; 4 having ophthalmoplegia and optic neuritis; 4 were cases of hypochondrical melancholia, and of these 3 temporarily improved, the other was a morphin case; 2 were cases of tabes with emotional weakening as the only mental failure, and there was one case each of slight dementia, melancholia, and dementia paralytica of senile form. The type of mental disorder in the 17 cases of paresis was expansive in all except two; marked confusional condition was present in the two depressed cases, and in nine of the expansive cases, confusion was also a prominent feature.

Removal of Foreign Bodies from the Air Passages.—The conclusions presented by De Forest Willard are as follows: (1) Coughing should be encouraged; forcible inspiration restrained; (2) Inversion in the prone position as a domestic practice is advisable; (3) Laryngoscopy is helpful if the body is lodged at the vocal cords. It may be extracted by forceps or by laryngotomy; (4) If time permits, the *x*-ray may be brought into serviceable use for diagnosis; (5) Careful diagnostic investigation is important to determine the actual presence of an impacted body, and its location; (6) Tracheotomy under local anæsthesia should be the rule, if the object is lodged at the bifurcation or in the bronchi. Tracheoscopy, suction and forceps' manipulation must be cautiously employed. Prolonged instrumentation adds greatly to the danger of pneumonia; (7) If extraction is not secured through the tracheotomy wound, the chest wall should not be invaded unless an artificial respiratory apparatus like the Fell-O'Dwyer is at hand, and oxygen available. With the assistance of these appliances, however, the bronchus may be reached, anteriorly or posteriorly, since, by their use, rhythmical movements can be maintained; (8) Resultant abscess of the lung should be treated by incision and drainage.

Somatic Signs of Brain Syphilis.—H. T. Patrick lays down the following postulates: (1) Brain syphilis is most frequent in the first year after infection, next most frequent in the second year, less frequent in the third year, and so on, about 50 per cent. of all cases occurring within three years after the primary sore. After ten years of quiescence, therefore, the appearance of cerebral syphilis is exceptional; (2) In reaching a diagnosis of a brain case, absence of a history of specific infection should have no weight in the case of women, and in the case of men relatively slight importance; (3) Syphilis of the brain is not synonymous with gumma; (4) Most frequently, brain syphilis means syphilitic arteritis. Next in frequence come syphilitic meningitis and syphilitic infiltration of the cranial nerves, while a gumma comparable to a brain tumor is least frequent; (5) Paralysis from brain syphilis (excluding paralysis of the cranial nerves) is most frequently caused neither by the pressure of a gumma nor by hemorrhage, but by thrombosis due to syphilitic arteritis; (6) Consequently, many cases of syphilitic paralysis are no more amenable to treatment than are those of cerebral thrombosis due to ordinary arteriosclerosis and atheroma (influence of age excepted), which means that the important symptomatology is that which proceeds and presages paralysis, because it is at such time that prompt treatment obtains brilliant, almost miraculous, results; (7) Syphilis is never a "system disease." As the Anglican sage, Sir William Gowers, puts it: "As a general rule, if we find certain structures of common function selected for isolated impairment from among others of different function, we may be sure that we have not to deal with a true specific process." There is no distinctive type of symptoms, but a sequence of signs illogical as regards both time and localization. A bizarre appearance, disappearance, reappearance, amelioration, and aggravation should excite suspicions of lues. Headache is present in about 75 per cent. of cases. Distinct attacks may assume the form of syncope, dizziness, momentary loss of consciousness, localized numbness, or spasms slight or severe, local or general. Cranial nerve paralyses are common. Alterations may be found in the visual field. Cranial nerves below the eighth are attacked less frequently than those above. Spinal-cord symptoms may be added, and there may be an impending or accomplished thrombosis. There is frequently a somnolent, semi-stuporous condition, while fever is regularly absent; vomiting is frequent, insomnia is not unusual, and there is a polydipsia, less often a polyphagia.

Syphilis of the Nervous System; Its General Pathology and Treatment.—F. W. Langdon says that the pathological processes concerned in syphilis of the nervous system comprise: (1) A localized parenchymatous and interstitial neuritis at the site of the initial lesion, due to endarteritis, compression, local and toxic action; (2) A localized root neuritis (cranial or spinal) and a peripheral mononeuritis, both of gummatous type, may occur in the secondary stage. (3) A generalized toxæmia affecting the nerve centers directly or metabolism in general and producing febrile reaction of a specific type, *i. e.* secondary fever; (4) Inflammatory (gummatous) lesions, due to disseminated or localized vascular infections. The arterial walls are the chief seat of these gummatous exudations, and the exudate may begin as a periarteritis, a mesarteritis or an endarteritis, eventually in most cases becoming a panarteritis. (5) Gummatous lesions are, in a measure, self-limited, their growth being checked by: (*a*) Central necrosis, due to deficient vascularity; (*b*) The probable development of an antitoxin which checks the local proliferation of microbes; (*c*) Fatty degeneration and absorption of the fluid portions with caseation or cicatrization of the remainder. (6) Degenerative nervous processes, due directly to syphilitic exudations, are of two types: (*a*) Compression degeneration, due to prolonged pressure by gummatous masses or their cicatricial sequelæ, which separates various neuron processes from the influence of corresponding trophic centers (neuron bodies); (*b*) Secondary degeneration, consequent upon destruction of the same neuron bodies by softening, of thrombotic or hemorrhagic origin; (7) Degenerative diseases of systematized type, such as locomotor ataxia and paresis. These should probably be looked upon as malnutritional affections due in part to arterial degeneration (fibrous or hyaline, or both) which may or may not be of syphilitic origin; and in part to inherent individual predisposition to early dissolution of certain physiological systems; (8) Remedies of value in syphilis may act in three ways: (*a*) The most usual, by promoting necrosis in the embryonic cells of the exudate, thus permitting their removal in large part by the lymph channels; (*b*) By stimulating the excretory organs generally, thus favoring removal of toxins produced by the disease; (*c*) Possibly by the promotion of leucocytosis and other tissue changes, which set free an increase of the natural amount of (hypothetical) antitoxin; (9) Any lesion of the nerve centers, attended or followed by inflammatory exudate, whether syphilitic or non-syphilitic, may be favorably influenced by the judicious administration of mercurials and iodides; and subsequent amount of damage by cicatricial compression or irritation may be materially lessened; (10) The discovery of a means of producing artificially an antitoxin which shall arrest the disease in an early stage must be conceded as a possibility.

American Medicine, Oct. 26, 1901.

Venesection in Puerperal Eclampsia.—F. D. Merritt has had excellent success with this method. His personal experience with puerperal eclampsia is limited to five cases. In four of these venesection was used and the four patients recovered. The treatment before this measure was tried was rapid delivery under chloroform anæsthesia, followed by hot packs, and pilocarpine muriate hypodermically, with chloral hydrate when indicated. The writer believes that watching the con-

dition of the arteries and heart is of more importance than testing the urine for albumin in guarding against puerperal eclampsia.

Sprinkling to Reduce Temperature.—W. L. Powell describes Cohen's method as follows: A large rubber sheet is placed beneath the patient with the lower part so folded as to direct the water into a receptacle on the floor at the foot of the bed. The head of the bed is raised about a foot. The patient is covered by a sheet folded to the proper size. The sprinkling is done by an ordinary watering pot with rose attachment. The temperature of the water used is between 60° and 70° according to the temperature of the patient. When the temperature is above 104°, an ice rub may be given besides the sprinkling. The shock from this method is much less than that from tubbing.

Chorea with Partial Paralysis Secondary to Rhinitis.—C. Fontaine-Maury Leidy reports the case of a Russian Jewess aged nine years. The child suffered from chronic catarrh of the nasal tract. About six weeks before she was brought to the writer, she began to be very restless and exhibit choreic movements of the face, shoulder, and right arm. Later, there was a complete loss of power of the right arm and hand, with dragging of the right toes. The nasal tract was irrigated with a slightly stimulating saline solution, applications were made to the tonsils, and directions were given to douche the nasopharynx twice a day. Internally, sulphate of quinine, one grain, was given three times a day. There was marked improvement. Treatment was stopped by the parents, and the symptoms returned. The same treatment was again instituted, with the addition of three drops of tincture of chloride of iron three times a day. Rigid treatment was insisted upon, and five and one-half months after the first treatment there were no symptoms of a choreic nature. The partial paralysis and choreic movements were probably due to septic infection from the nasal tract, with imperfect oxygenation of the blood dependent upon the obstructed air passages.

Medical News, October 26, 1901.

Biopsy; The Histological Diagnosis of Dermatoses and Tumors of the Skin of Doubtful Character.—Jean Darier defines biopsy as the excision of an eruptive lesion or a fragment of tumor for the purpose of establishing the diagnostic histology of a malady. Its indication is the discovery of a lesion of the skin, or an accessible lesion of the mucous membrane, of which definite diagnosis can be made in no other way. Biopsy is indispensable in the case of tumors and ulcers of doubtful character which tend to invade surrounding tissues. There are other cases not so pressing, such as a persistent eruption of indeterminate character. In special cases the writer has resorted to biopsy for the diagnoses of common dermatoses. One of the most important indications for biopsy is in the diagnosis of epitheliomata. The vague class of "tuberculides" almost always require this method for a definite diagnosis. Finally, by biopsy, the diagnosis of various dermatoses and cutaneous tumors, which is by other means impossible or doubtful, may be definitely established.

Four Cases of Tumors.—James E. Newcomb reports these cases. The first patient was a colored man aged forty-one years. He had a constant and increasing obstruction of the right naris. There had been neither pain nor hemorrhage. There had been an irregular moderate post-nasal discharge. Examination revealed an apparently bony adhesion between the inferior turbinate and the septum, beginning about three-quarters of an inch from the vestibule and running backward for half an inch. The obstruction was removed with great relief to the patient, but in a few weeks the growth returned. Sections were made and examination showed the tumor to be a true osteosarcoma.—The second patient was an American aged fifty-five years. He suffered from severe epistaxis. The nasal septum was strongly bulged to the right, and on its convexity was a large erosion from which the blood came. On the left side of the septum, at its top, just at the junction with the ala, was a small cauliflower-like mass. It had given no symptoms. It proved to be a true papilloma.—The third patient was an American aged sixty-five years. He complained of a "swelling in the throat." A tumor occupied the right side of the throat, extending from opposite the last molar tooth upward and inward to beyond the median line, downward to the floor of the mouth, and backward into the pharynx. It was tense, elastic, and smooth, with one or two harder spots on its surface. It proved to be a telangiectatic sarcoma of the bronchial cleft with hyaline degeneration; the lymph nodes were hyperplastic; there was no tonsillar tissue. It was removed with success.—The fourth patient was an American of Irish parentage, aged twenty years. He had been troubled by nasal stoppage. There was a mass in the nasopharynx reaching back from the choanæ. The growth proved to be an angiomatous fibroma. This growth apparently originated from the general region of the middle turbinate.

Philadelphia Medical Journal, October 26, 1901.

Some Respiratory Conditions Dependent upon Gout and Obesity.—J. M. Anders states that the abnormal conditions of the lungs in obesity are caused principally by the mechanical effects of the deposits of fat throughout the body. Dyspnœa is more marked in the anæmic than in the plethoric variety of obesity. A hyperæmic bronchitis with troublesome cough and often copious mucoid expectoration is common in obesity. The physical signs are variable. Hepatic enlargement may also arise as a secondary event in obesity. The writer concludes concerning the relation of asthma to polysarcia: (1) That asthma occurs in about 5 per cent. of the cases of obesity; (2) That it only occurs in extreme polysarcia; (3) That there is present a gouty state or history in most cases in which true asthma is secondary to obesity; (4) That about one-half of the cases are curable by overcoming the causative condition. Gout and obesity are closely associated. Asthma may be directly dependent upon the transient irritant action of the uric acid in the circulating medium, and is one of the nervous phenomena of gout. In order to treat these cases, it is necessary to recognize the cause so that the line of conduct may take cognizance of the lithæmic state.

Multiple Primary Neoplasms in One Individual; Treatment with Coley's Mixture.—Aldred Scott Warthin reports this case. The patient was a man aged seventy-three years. He presented himself for the treatment of a tumor on the inner side of the right forearm. The clinical diagnosis of sarcoma was confirmed by the pathological examination of an excised part. It was a large spindle-cell sarcoma. As the case was considered hopeless, injections of Coley's fluid were tried. The reaction to this treatment was decided, and large areas of necrosis were produced. Nevertheless, the growth increased and soon the entire forearm was involved. The patient grew rapidly worse till death occurred. At autopsy the presence of various neoplasms and lesions throughout the body was discovered. The tumor of the arm was a primary spindle-cell sarcoma, which had formed metastases in the right axillary glands. There was primary adenocarcinoma of the pylorus. In the stomach wall were multiple myomata. Atrophy and parenchymatous degeneration of all organs were present. The coincidence of carcinoma and sarcoma must be considered merely as an interesting pathological curiosity. The fatty degeneration of the intima of the blood vessels, heart, voluntary muscles, and the parenchymatous changes were caused by systemic poisoning. This may have come from the absorption of poisons from the necrotic parts of the sarcoma, or from the injections of the toxins. The destruction of a tumor by the injection of toxins is attended by the danger of systemic intoxication and the more rapid development of cachexia. There is also a possibility that large injections favor metastasis by mechanically loosening the cells of the tumor into the lymph current.

The Lancet, October 19, 1901.

On the Protective Substances of Immune Sera.—E. W. Ainley Walker asserts that if the M. L. D. (minimum lethal dose) of a given bacterial culture be determined, and the dose of immune serum necessary to protect against this M. L. D. be called its serum equivalent, it has been observed that if an animal be now given two M. L. D. and two serum equivalents, it is not protected, but dies from the infection. This has been explained as due to a deficiency of addiment in the animal concerned, but in reality it is only due to a deficiency in the amount of immune body given in the immune serum. He concludes by saying that (1) Addiment is not extremely special to the species; (2) Addiment is a leucocytic ferment; (3) Addiment is increased during and by immunization; (4) The immune body is produced exclusively by the leucocytes; (5) Agglutinins assist the phagocytic process.

The Treatment of Hemiplegia.—L. G. Guthrie summarizes the principles of treatment in the following propositions: 1. Neglect and want of treatment aggravate severe, and retard the recovery of mild, cases. 2. The evils to be foreseen and guarded against are articular adhesions, late rigidity, and muscular atrophy. 3. Articular adhesions should be prevented by passive movements of each joint from the very first. 4. Faulty positions of the

limbs should be constantly corrected, or they will become chronic. 5. Contraction of muscles should be treated by endeavors to improve the nutrition of their weaker opponents. 6. Massage, passive movements, and, to a less extent, electricity should be used with this object. These agents not only counteract muscular atrophy from disuse, but probably take the place of normal stimuli and invigorate the neurons. 7. The recovery of mild cases may be often hastened by re-education of movements. Want of re-education frequently prevents recovery. 8. Re-education consists in a combination of passive and active exercises. 9. Movements should be first encouraged in those parts which naturally tend to recover first. 10. Incoördination and general weakness of limbs which have yet regained power of movement should be treated by exercises and mechanical therapeutics. 11. It is important to find out what the patient can do, and to make him do it. In conclusion, this paper deals with the treatment of hemiplegia as a condition without reference to its cause, for whether the cause be hæmorrhage or occlusion of cerebral vessels by embolism or thrombosis is immaterial. The principles of treatment will be the same and need not interfere with other measures taken for the relief of the disease which gave rise to the hemiplegia.

British Medical Journal, October 19, 1901.

Paralysis Following Influenza in Young Children.—Catherine Smith has noted in five cases of influenza in children that paralysis has set in in periods of from ten to twenty-one days after the influenza had run its course. There were muscular wasting and inability to move the limbs. In about two months all the cases recovered. The treatment consisted in the administration of tonics and massage.

An Unusual Form of Keratitis Associated with a General Skin Eruption.—Charles S. Blair describes the case of a young man of eighteen years who shows on the inner and outer side of each cornea a raised, vascular, opaque, and firm swelling, involving the limbus and the adjacent part of the cornea. The swelling is stationary and symmetrical. There has been no ulceration, and the rest of the cornea is free from any signs of former keratitis. There are no signs of any lesion of the palpebral conjunctiva, no iritis, no cyclitis, and the vision in each eye has remained perfect. From time to time there are exacerbations, when the eyes are painful and the swellings are larger and more injected. At these times, the body has become covered with a papular and pustular eruption, causing so much irritation as to prevent sleep. Although these growths on the limbus have some characteristics which resemble "spring catarrh," they differ in other respects from this affection. Whether related to spring catarrh or not, this eye lesion is without doubt a part of the general skin affection, and both are the result of a common cause—some constitutional dyscrasia or trophic disturbance.

A Case of Symmetrical Bullous Keratitis.—J. Tatham Thompson reports this case in a man aged twenty-two years. He had suffered with intense photophobia for about three weeks. The general health was good, and he had never before suffered with any eye trouble. This present condition had begun in both eyes at the same time, with a sensation of dust, burning pain, followed by photophobia and lacrymation on the second day. There was no sticking of the lids. In order to make the examination, cocaine had to be freely used. The conjunctivæ were slightly congested, and on both corneæ was a ring of oval bullæ radiating from about midway between the center of the cornea and its periphery, about twelve or fourteen in number, and oval. They were of a pale pearl color. The center of the cornea was clear V. about 6/12 R. and L., and he read Jaeger No. 1. After pricking one of these bullæ, it seemed but little changed. The writer used warm solution of boric acid and mercury perchloride, boric acid and alum, etc., but there was no improvement. He then used solution of formol $\frac{m}{xxxx}$, and cocaine and atropine. The photophobia gradually subsided, and four months from the onset the patient was able to resume work. A ring of semiopaque spots was left. At first, there was a great deal of frontal neuralgia, which suggests a possible herpetic origin.

Discussion on the Diagnosis, Prognosis, and Treatment of Pernicious Myopia.—Priestly Smith states that myopia in some cases is an innocent condition not leading to disaster of any kind, while in other cases is it a pernicious condition which leads sooner or later to serious impairment or loss of sight. In the attempt to predict the course of any case, the chief data on which the forecast must be based are as follows: (1) The age; (2) The grade of myopia; (3) The condition of the choroid and retina; (4) The constitutional condition; (5) The evidence relating to heredity; (6) The occupation of the patient. As to the age, all things being equal, the younger the patient, the more likely is the myopia to increase in degree. As to the degree, other things being equal, the higher the myopia, the more likely it is to increase. The average vision of myopes sinks as the grade of the myopia rises. Cases of rapidly progressive myopia associated with malnutrition are not uncommon. Constitutional disease may be a factor in any case of myopia. The tendency to myopia is very frequently hereditary. The future of many myopic eyes depends on the way in which they are used. The duty of the oculist should be to suspect every myopia, especially every youthful myopia, of a tendency to increase, until time has proved it to be stationary; to be doubly suspicious in presence of congestion or atrophy; and to re-examine at intervals of six months, twelve months, or longer, according to the nature of the case.

Berliner klinische Wochenschrift, October 7, 1901.

Are the Lymphocytes Capable of Amœboid Motion?—H. Hirschfeld answers in the affirmative, basing his conclusions on some observations made according to the methods of Deetjen. The drop of blood is caught upon a cover-glass, and is then dropped in a solidified film of agar spread on a slide. The agar is a modified solution prepared by adding to each 100 c.c. 0.6 gr. of sodium chloride, 6 to 8 c.c. of a 10-per-cent. solution of sodium metaphosphate, and 5 c.c. of a 10-per-cent. solution of dicalcium phosphate. Under these conditions, it was found that the lymphocytes in a case of lymphatic leukæmia rapidly lost their circular contour and extruded short processes. These movements gradually became more active, and finally resembled those that have already been described for the polymorphonuclear neutrophiles. The results of a study of the blood of normal individuals are not yet ready for publication.

The Collapse of the Lung in Pneumothorax, with Observations on Double Pneumothorax.—Dr. Hellin says that the following views have prevailed concerning the intrathoracic phenomena attending puncture of the pleura: (1) The lung collapses completely after even the smallest wound of the thorax; (2) The size of the wound is of importance only as the rapidity of pulmonary collapse is concerned; (3) The lung collapses only when there is a good-sized opening into the pleura; according to some authors only when the wound is greater than the cross-section of the trachea; (5) The complete collapse of the lung depends in part on the location of the pleural wound; (6) The lung does not collapse completely, for even in the collapsed lung, fluctuations of pressure take place; (7) The lung does not collapse completely, but continues in motion after the opening of the pleura; but these movements are not sufficient to pump air into the lung. The author thought that the question could be solved by determining whether it was possible to keep alive animals with a double pneumothorax. If this could be done, it would prove that the collapse of the lung was not complete. He, accordingly, experimented on rabbits in various ways, and from his observations draws the conclusion that a complete collapse does not take place when the pleural cavity is opened even by a very large wound.

Münchener medicinische Wochenschrift, October 8, 1901.

The Treatment of Finger Injuries, with Especial Reference to Later Function.—H. Georgi is an advocate of radical treatment in injuries of the fingers, since conservatism too often leads to bad results in the way of tender scars, cicatricial contraction, slow healing, and above all of the development of "glassy skin"—a state of local malnutrition due to the imperfect blood supply. For the workingman especially, it is always preferable to resect projecting bone ends freely, and secure material for abundant well-nourished flaps of healthy tissue, which will heal quickly by first intention, and not give rise to subsequent cicatricial deformities.

The Appearance of Psoriasis Vulgaris Secondary to Tattooing.—Bettmann's patient was a healthy middle-aged man with a past and family history negative for all skin diseases. Two weeks after a large piece of tattooing was done on his forearm, a typical psoriasis started in the area operated on and gradually spread over the entire body. The tattooed surface was outlined with great accuracy and wholly occupied by a dense efflorescence, while the site of a tattooing done three years previously showed only a single small patch. The author holds that the occurrence of the skin lesion so soon after the cutaneous trauma and its originating in the irritated area are more than a coincidence, and he cites the case as evidence of the parasitic nature of the disease.

A Case of Retained Consciousness in an Epileptic Attack.—A. Diehl was consulted by a patient who described to

him a convulsive seizure he had passed through the night before. This attack was similar to numerous others he had had, and like these was brought on by the consumption of a moderate amount of alcohol, of which he had been growing more and more intolerant. The fits were always nocturnal and inaugurated by an aura of several seconds, which time he had learned to utilize by moving away from the edge of the bed and drawing his tongue into the back of his mouth—a precaution he always took, though he usually bit the organ nevertheless. Immediately afterward the seizure began, and he went through the phases of an ordinary epileptic attack. All of the details of the fit, the rolling of the eyes, the position of the hands, and rotation of the head, were clearly appreciated and remembered, and after a heavy sleep for the rest of the night, he would awake the next morning stupid and fatigued. The author considers the diagnosis of nocturnal epilepsy justified, and comments on the rarity of the preservation of consciousness during such attacks.

The Flushing of the Organism in Experimental Tetanus.—C. Tonzig, working on the theory that the toxin of tetanus differs from such poisons as strychnine and similar alkaloids in the slow development of its action, undertook to determine whether it was possible to remove the toxin from the body before it had had time to develop its full power. The poison of tetanus acts by producing definite anatomical changes in the nerve cells, and is able to do this only when it encounters some antagonistic substance with which it can combine and so form the tetanic virus. With the idea of washing out as much of the poison as possible before it had time to enter into such combinations, the author injected large amounts of salt solution into the peritoneal cavities of infected rabbits, and came to the following conclusions: (1) The use of peritoneal injections of salt solutions does not always lead to a favorable termination in tetanus. (2) The experiments showed that the tetanus poison acts, not while circulating, but by entering into the tissue elements. (3) Unless the introduction of the toxin is at once followed by the development of symptoms, the flushing out of the body by such an artificial serum retards their occurrence and may defer death for several days. This measure, therefore, ought always to be considered, especially when it is not immediately possible to employ serum therapy.

Deutsche medicinische Wochenschrift, October 10, 1901.

Neuroglia Growth.—Victor Babes says that it is one of the chief functions of neuroglia to supply the tissue lost in pathological states through cessation of the proliferative resistance of the parenchyma, but the part played by this tissue in neoplastic processes is also important, since the neuroglia may increase independently of any parenchymatous degeneration, and even in spite of proliferation of the parenchyma. Still, it may be true that the first impulse to new growth often arises in an injury or weakening of the parenchyma through trauma or infection, the neuroglia overgrowth going on to obliterate these conditions and advance steadily. The communication closes with a tribute to Virchow's genius, for while later researches have added minor details to his observations, the main facts concerning this tissue still stand as they were first described by him.

The Portals of Entry for the Tubercle Bacillus and its Localization in Man.—P. Grawitz considers the question of the liability to infection through the use of milk from tuberculous cows, and states that the first point to be solved is what proportion of those dying of tuberculosis were infected through the consumption of food containing tubercle bacilli. Among the difficulties complicating the matter is the fact that just as there is an individual predisposition, so there is also a predisposition of organs. For example, the comparative rarity of tuberculous laryngitis shows that the laryngeal and tracheal mucosa is but little adapted to serve as a channel of entrance for the organism, and that these tissues are particularly resistant. When the intestine is found to be actually tuberculous, the question arises whether the lesion is primary and likely to be of alimentary origin, or whether there are also mesenteric or pulmonary lesions which make a lymphatic propagation of the infection probable. If the tubercle bacilli shown to be so common in butter and milk were really virulent for the human organism, we should expect to find such cases of primary enteric lesions with great frequency, instead of which they are very rare. The intestinal mucous membrane does not belong to the more susceptible tissues, and is often found intact when the mesenteric glands are involved and tuberculous sputum has been swallowed for years.

French Journals.

Employment of Gelatinized Serum in Hemorrhagic Pleurisies.—Raymond Bernard presents these conclusions: Gelatinized serum extends its hemostatic efficacy to hemorrhagic pleurisies. Its employment seems to modify the amount of fibrin in the pleuritic exudate. The local and general reaction which it excites is temporary and not troublesome. The action of the serum on tuberculosis itself is neither favorable nor unfavorable; it is *nil.—Lyon Médical, October* 13, 1901.

The Influence of the Variations of Temperature in the Evolution of Experimental Tuberculosis.—Lannelongue, Achard, and Gaillard conclude that neither a moderate degree of cold nor slight variations have had any marked influence on the variations of temperature in the animals experimented on. On the contrary, however, sudden and considerable changes, although compatible with the life of healthy animals, have hastened the course of infection in the most striking manner.—*Le Bulletin Médical,* October 16, 1901.

Central Tear of the Perineum Giving Passage to an Arm.—Pujebet and Stérin report this case in which the child's arm protruded through a central tear in the perineum, while the head presented at the vulvar orifice. They enumerate several factors which have been regarded as active in the causation of central tears of the perineum. (1) In the formation of the bony pelvis; abnormal slant of the sacrum and coccyx; undue height of the symphysis pubis; slight inclination of the pelvis; narrowness of the pubic arch. (2) In the formation of the soft parts; extreme length of the perineum; abnormal form of the vulva; rigidity of a persistent hymen. Poor quality of tissues, rapidity of expulsion, and irregularity of uterine contraction and of the expulsive efforts of the patient may also play a part in this curious accident.—*Journal des Sciences Médicales de Lille,* October 12, 1901.

Surgery of the Turbinate Bones.—J. E. Boylan concludes from a study of 111 turbinotomies, that while in exceptional cases there may be involvement of the whole erectile surface of the dependent portion of the turbinate, still the hypertrophy is habitually greater where the tissue is more abundant; for example, at the posterior and anterior extremities; that the amelioration of the obstruction and the reduction of the hypertrophy in these cases are obtained more surely and more scientifically by ablation than by cauterization; that if the venous dilatation is greater at the posterior extremities, the obstruction is rarely due to hyperplasia of this one point. The writer believes that ablation is far preferable to cauterization in these affections. For cauterization, sufficient to materially reduce the hypertrophy, will necessarily destroy the glands so essential to the exercise of the function of the turbinates.—*La Pratique Médicale des Maladies des Oreilles, du Nez et du Larynx,* August 15, 1901.

Histological Examination of a Lymphatic Cyst of the Conjunctiva.—Cabannes first mentions the interesting fact that in the ground substance of this cyst, which consists of coagulated albuminoid material, there is a considerable number of leucocytes and, particularly, lymphocytes. At one point of the section of this cyst, the conjunctival epithelial layer is modified, being composed of several layers of cylindrical cells, those in the depths being ovoid, while the superficial ones are flat. In the subjacent derma are wavy fibers, scattered nuclei, and some turgescent blood-vessels. At one point the derma is thin, its fibers appear distended, and its meshes are complicated. At one point near where the injection has been made, there is a large, distended lymphatic vessel containing a granular substance resembling coagulated albumin. This tumor is more exactly an inflammatory lymphangioma than a lymphatic cyst. The opportunity for a microscopical examination of liquid conjunctival cysts does not very often present itself.—*Journal de Médecine de Bordeaux,* October 13, 1901.

The Action of Fatigue on the Minute Structure of the Nerve Cells of the Spinal Cord.—By his experimental researches, Guido Guerrini has found that the spinal nerve cells of exhausted animals are in their minute structure different from the cells of animals in a normal condition, this difference being in direct relation with the grade of fatigue undergone. The quality of the alterations cannot be considered specific of fatigue, nor are they found in any special location in the spinal cord. They may be found in either anterior or posterior cornua, or in both. The minute changes of structure of new cells in the cord are never so marked as in the cells of the cortex. The author gives further details of his experiments and their results.—*La Riforma Medica*

Book Reviews.

THE PRINCIPLES AND PRACTICE OF MEDICINE. For Use of Practitioners and Students of Medicine. By WILLIAM OSLER, M.D., F.R.S., F.R.C.P., London; Professor of Medicine Johns Hopkins University. Fourth Edition. New York: D. Appleton & Co., 1901. 8vo, pp. 1182.

THERE is no question as to the real worth of this textbook. Professor Osler is so well appreciated as a sound and practical teacher that anything bearing his name carries the weight of the highest authority. The previous editions have fully attested this fact, and the present one is in full line with the others. As it stands, it is an up-to-date book in every essential particular. Very many important changes have been made in keeping with advancing views on many of the leading diseases. The article on typhoid fever has been in great part rewritten. Dysentery, yellow fever, and plague have been similarly treated. Diabetes and gout have been much elaborated in their discussion by the addition of the experience of the author's clinic. The same may be said for diphtheria, which incorporates the model work of McCollum and Councilman in the Boston City Hospital. On smallpox, cerebrospinal fever, rheumatic fever, and many others of the acute infections, new points on diagnosis and treatment are added. Practically new articles are those on "Diseases of the Pancreas," "Splenic Anæmia," "Arsenical Poisoning," "Herpes Zoster," "Fibrinous Bronchitis," "Oxaluria," "Menière's Disease," "Aphasia," "Combined Sclerosis of the Cord," "Myasthenia Gravis," "Congenital Aneurysm," and "Scurvy."

The general plan of the work is well preserved in spite of these additions, giving to the practitioner a terse, well-written, practical, and comprehensive treatise on internal medicine. On the whole, there is an individuality about the work which gives it charm, force, and directness.

SEXUAL HYGIENE. By the Editorial Staff of the Alkaloidal Clinic. Chicago: Clinic Publishing Co., 1901. 12mo, pp. 269.

THIS little work, intended solely for the profession, necessarily deals with some very plain facts connected with the subject under discussion. On the whole, the treatment of the various topics is dignified and practical, and although no strikingly original views are offered, they are nevertheless presented in a candid and straightforward manner well calculated to impress the reader. Behind all there is a healthy moral tone about the book, which appeals to the good sense of all seekers after truth and fact.

HOLDEN'S ANATOMY. A Manual of Dissection of the Human Body. Edited by JOHN LANGTON, Lecturer on Anatomy, St. Bartholomew's Hospital, Seventh Edition, revised by A. HEWSON, M.D., Demonstrator of Anatomy, Jefferson Medical College, Philadelphia. P. Blakiston's Son & Co. 2 vols., 12mo, pp. 843.

THE last edition of this standard work comes in two volumes instead of one as formerly. A few alterations have been made in the text, but the general character of the book is still maintained throughout, which is saying all of good that can be said of an anatomical classic.

MT. SINAI HOSPITAL REPORTS. Vol. II. 1899–1900. Edited for the Medical Board, by PAUL F. MUNDÉ, M.D., LL.D., 1901.

THIS is much more than an ordinary financial and statistical report of hospital work. Rudisch, Manger, Brill, May, and Koller give interesting reports and scientific papers, while Gerster and Lilienthal report on the surgical work at great length.

DIE KÜNSTLICHEN NÄHRPRÄPARATE UND ANREGUNGSMITTEL. Von Dr. MAX HEINE in Bonn. Berlin: August Hirschwald, 1901.

THIS unbound work of 230 pages gives an insight into artificial food products, and discusses at some length the therapy by diet, and as an appendix, beginning at page 170, gives the various "cures." The ground is well covered.

LA LÉPROSE. Par Le Dr. DOM SANTON, Paris. C. NAUD, Editeur. 1901.

THE author has gone about this rather pretentious work in a systematic manner, first visiting the chief leprous centers of the world before settling down to the task of placing his views on printed page. The work is dedicated to Pasteur, who first and more than any other encouraged him in his long and laborious undertaking. He makes four periods of the typical disease, much after the manner of dividing syphilis: incubation infection or primary accidents, secondary accidents, and tertiary accidents. The anatomical and clinical study of the affection has influenced to this division rather than any desire to draw a parallel with syphilis. The historical portion is of much interest to the student, and the demonstration that lepra has in various ages been confounded with other affections but this does not, we opine, warrant the attempt to do away with the older term, and substitute for it that of *léprose*. In this the author falls into the easy error French writers make in striving to place all medical terms on a French basis. Coming down to the practical portion of the work, prophylaxis has received the important place it deserves, and a rational and scientific mode of treatment has been advocated, based upon a therapy which consists in "knowing what one does and why it is done." The volume is well illustrated with plates and sixty figures (some colored) in the text, besides a map.

TRANSACTIONS OF THE AMERICAN MICROSCOPICAL SOCIETY. Edited by the Secretary. Twenty-third Annual Meeting Held in New York City, June 28, 29, and 30, 1900. Vol XXII. Lincoln, Neb.: State Journal Co., 1901.

AFTER the address of the president, A. M. Bleile, on "The Detection and Recognition of Blood," there follow a dozen papers, interesting to the naturalist as well as the microscopist, and a few of importance to the physician, especially those on water impurities. The volume is octavo, and contains 228 pages. The society is deserving of congratulations. The necrological notice of Jacob Dobson Cox of Ohio is accompanied by a full-page portrait.

THE MICROSCOPE AND ITS REVELATIONS. By the late WILLIAM B. CARPENTER, C.B., M.D., LL.D., F.R.S. Eighth Edition, in which the first seven and the twenty-third chapters have been entirely rewritten, and the text throughout reconstructed, enlarged, and revised by the Rev. W. H. DOLLINGER, D.Sc., D.C.L., LL.D., F.R.S., etc. With twenty-two plates and nearly nine hundred wood engravings. Philadelphia: P. Blakiston's Son & Co. 8vo, pp. 1,181. 1901.

IN this, the eighth edition of "The Microscope and Its Revelations," the editor has added such additional information which recent years have contributed to the subject under treatment, and practically all of which is needed to be known by the ordinary worker. To the medical student or practitioner who desires to know the theory of microscopy, and with a wish to obtain the best results with that instrument, the work will prove invaluable. There is much admirable work in the numerous plates and wood engravings which will stimulate popular interest in the use of the microscope as a pastime and a means of relaxation, and to the beginner the clearness and completeness of the instruction will specially appeal. Mounting specimens, section-making, imbedding, and staining are well explained, and to one who is unable to obtain a personal teacher this volume may be safely recommended as a guide.

The author has obtained great uniformity in his work by overseeing and rewriting the whole text in person, and in some instances having his words and descriptions criticised by the original observer. To do this he has evidently spared no pains, and has called to his help a large number of specialists in the different fields of microscopy, notably Dr. Abbe of Jena, E. M. Nelson, W. J. Popé, F. Jeffrey Bell, and many others. One cannot avoid commending the numerous plates which add so much to the practical value of this edition. To one contemplating the purchase of an instrument a full list of English, Continental, and American microscopes is described in text and drawing with their peculiarities and advantages. The topics in the latter part of the work are in the fields of biology, botany, bacteriology, chemistry, and geology, thus affording a breadth of subjects which appeals to many workers with widely different interests.

THE PRINCIPLES OF HYGIENE: A Practical Manual for Students, Physicians, and Health Officers. By D. H. BERGEY, A.M., M.D., First Assistant, Laboratory of Hygiene, University of Pennsylvania. 8vo, 504 pp., illustrated. Philadelphia and London: W. B. Saunders & Co., 1901.

THIS book is stated by the author to be intended to meet the needs of students of medicine in the acquirement of a knowledge of those principles upon which modern hygienic practices are based, and to aid physicians and health officers in familiarizing themselves with the advances made in hygiene and sanitation in recent years. To attempt to meet the quite dissimilar needs of medical students and experienced sanitarians between the covers

of a single small volume is necessarily to invite failure—and this, to a certain extent, has befallen the labors of the author of the book in question. Regarded as a work of reference for health officers, Dr. Bergey's book would seem to be in large part of too elementary a nature to be of value for such purposes, and markedly inferior, in this respect, to Harrington's "Practical Hygiene." As an elementary textbook for medical students, the book is more of a success, though it contains much material which is obviously of little interest or value to the medical student. Thus, of the total 463 pages of text, no less than sixty-seven are devoted to the setting forth of quarantine regulations, as quoted from official documents. From this and other facts it would seem that the book, small as it is, can scarcely be considered as free from the charge of padding. As a textbook for students, the book, on the whole, cannot be regarded as superior to Egbert's "Hygiene and Sanitation," second edition, written especially for this single purpose. With the two excellent books by the authors just named already in the field—both fresh from the hands of the printer, and in all respects up to date—Dr. Bergey's statement in his preface that "the rapid strides made in our knowledge of the entire subject of hygiene has rendered such a book [his own], based upon recent discoveries, almost a necessity," would scarcely seem to be substantiated. The literary style of the author is good, and his material is well put together; though he frequently does not give due space and emphasis to subjects whose practical importance should entitle them to more consideration, and conversely renders unduly prominent other subjects having a purely academic interest. The book is printed and bound in an attractive manner. We cannot, however, regard it as an important or very valuable contribution to the literature of sanitary science.

Manual of the Diseases of the Eye, for Students and General Practitioners. With 275 original illustrations, including 36 colored figures. By Charles H. May, M.D., Chief of Clinic and Instructor in Ophthalmology, Eye Department, College of Physicians and Surgeons, Medical Department, Columbia University, New York. Second edition. Revised. New York: William Wood & Co., 1901.

The short time that has elapsed between the appearance of the first and the second editions of this book attests to the value and popularity of the work. The new edition is much superior to the first, being improved in text and in illustrations. The volume is now one of 408 pages, and is fully and effectively illustrated. The chapters are arranged in logical order, and the descriptions are lucid and brief. The first thirty-four pages are devoted to directions regarding the examination of the eye, and theory and use of the ophthalmoscope. Then follows the description of diseases of the various parts of the eye and their treatment, medical and surgical. The consideration of general optical principles and refraction occupies seventy-three pages. Disturbances of motility are considered; a formulary and directions for bandaging are added. The work is admirably adapted for undergraduates in medicine, and is also of value to the general practitioner.

De L'Echinococcose Secondaire. Par Dr. Félix Dévé, Ancien Interne des Hôpitaux Paris, Société d'Editions Scientifique, 1901.

The subject of echinococcus infection has always been of great interest to the pathologist, though in this country opportunities for its study are not very frequent. The present work is a systematic study of the life-history and pathological manifestations of the organism. The author tells us that he has chosen the name "echinococcose" and has used a case as the basis of his study which has come under his own observation. He has made a number of experiments in peritoneal inoculation in animals and has given us the findings of the autopsies. A short chapter is devoted to the subject of treatment, which is chiefly prophylactic, and there is a useful bibliographical index, compiled mostly from Continental sources.

J. Boas: Diagnostik und Therapie der Magenkrankheiten. Theil II, 4te Auflage. Leipzig: 1901. Verlag von G. Thieme.

The fourth edition of Boas' excellent book on Diseases of the Stomach has just appeared. The present work contains numerous additions to the old text. Thus pylorospasmus, sarcoma, syphilis, and tuberculosis of the stomach, achylia gastrica, erosions of the stomach, and nausea nervosa have been inserted as new portions. The book is eminently practical, and is herewith recommended in the highest terms.

Society Reports.

NEW YORK STATE MEDICAL ASSOCIATION.

Fourth Day—Thursday, October 24

Surgical Malposition of the Gall-Bladder.—Dr. E. D. Ferguson of Troy reported three cases illustrative of malpositions of the kidney. In the first case, he had found at operation that the gall-bladder was situated behind the posterior border of the liver and was filled with calculi. In the second case, the gall-bladder was located at the posterior edge of the under-surface of the liver, behind the peritoneum, and occupied a transverse direction relative to the body. It was contracted on numerous calculi, and could not be brought at any point toward the anterior abdominal wall. In the third case, the gall-bladder was found extending from the lower surface and posterior border of the liver downward to the right of the spine and behind the colon.

Differential Leucocyte Count in Fractures.—Dr. William G Le Boutiller of New York presented a paper on this subject. He stated that in a series of fifty consecutive cases of simple fractures, recently observed, he had found a temperature often as much as three degrees above the normal. On the day of the injury, the lowest temperature recorded had been 98.4° F. and the highest, 102.4° F. In thirteen cases, the lowest temperature had been 100° or more; in thirty-five, it had reached or exceeded 100°, and in nine cases it had risen to 101°. On the second day as low a temperature as 99° had been observed in only thirteen cases; in twelve it had not gone below 100°; forty-one had had a maximum temperature of 100° or more; thirteen had had a temperature of 101°, and in two cases the temperature had reached 102°. The temperature had not become normal in any case before the third day, but had been normal on the tenth day in half of the cases. In 25 per cent. of all the cases, the temperature had been still above the normal at the end of two weeks, although no cause other than the fracture could be assigned. However, the temperature could not be depended upon as an index of the occurrence of infection in compound fractures, for it was often no higher in them than in closed fractures on the second or third day. The paper gave the results of sixty-five differential wounds in seventy-three simple fractures, and thirty-nine counts in ten compound fractures. These had been made at intervals after the injury, varying from a few hours to several weeks. In simple fractures, three counts on the first day had given 7,400, 9,400, and 10,200 leucocytes, respectively. Three counts made on the second day had given 6,000, 9,200, and 10,600. The counts on the sixth day had been 8,000, 9,200 and 11,000. In a compound fracture, in which the infection had only been slight, there had been 21,300 leucocytes on the third day. The ordinary leucocyte count, therefore, appeared to be a better test of infection than the temperature, though not quite reliable, as it might be as high in simple as in some infected fractures, and might be high in aseptic compound fractures, especially after the occurrence of hemorrhage. On the first day, the ordinary percentage of polynuclear neutrophiles had been high, averaging for four cases, counted on that day, about 85 per cent., while that of the leucocytes was less than 15 per cent. After the first two days, there had been an increase in the proportion of lymphocytes and a reciprocal decrease in the percentage of polynuclear neutrophiles. The percentage of eosinophiles had been within normal limits, *i. e.* 0.5 to 4 per cent., the highest count having been 6.6 per cent. In forty-one counts in twenty-one cases there had been fewer than 0.5 per cent. Eosinophiles had been absent at all counts in only two cases. Myelocytes had been noted in thirteen of the thirty-three cases, or in twenty five of the one hundred and four counts, and in six cases of the eight fractures of the femur. The appearance of the myelocytes in the blood had been

attributed to hyperplasia of the red marrow, or to mechanical dislodgment of marrow cells resulting from structural changes in the marrow, or from hydræmic states of the blood plasma. In conclusion, the speaker said that the results of the differential blood counts bore no appreciable relation to the temperature. They were practically the same in simple and compound fractures. They appeared to represent the presence and absorption of the blood effused at the time of the injury, and the stimulation of the bone marrow during the process of repair

Prostatic Obstruction to Urination; Its Remedy by Enucleation of the Diseased Parts.—Dr. J. W. S. Gouley of New York in this paper discussed the histology and pathology of prostatic enlargement, together with the results of enucleation. He also presented an instrument which he had devised to facilitate the performance of this operation.

Dr. Parker Syms of New York said that the high mortality that had attended the operation of enucleation of the prostate seemed to him to be largely dependent upon the fact that the suprapubic method was employed; hence, he had devoted his energy to perfecting a method by which the prostate could be removed entirely by the perineal route. To this end, he had devised a retractor, which, he thought, would make it possible to enucleate the diseased portion of any prostate through the perineal wound. By such an operation there would be a simple straight wound in the perineum, having a level floor, drainage would be assisted by gravitation, and the dressings could be easily made. In his small experience with this operation, the convalescence had proceeded without any untoward incident. Dr. Syms then presented his retractor. It consists of a rubber bulb on the end of a catheter-like tube. After doing a simple perineal section and opening the membranous portion of the urethra, the instrument is introduced into the bladder while collapsed. It is then distended by injecting two ounces of water. The dilated bulb thus acts as a retractor, and is entirely out of the way of the operator. It holds the bladder in place and draws the prostate toward the wound. It had acted very well in nearly a dozen cases in which he had used it. He had never observed that the instrument showed any tendency to tear the neck of the bladder.

Dr. Eugene Fuller of New York said that he sometimes removed the prostate by the perineal route, but in many instances he preferred the suprapubic route because it was possible to do a cleaner operation. If the prostate weighed half a pound or more, the operation of enucleation through the perineal route would be tedious, and long and severe operations should be avoided in these old men. If the bladder were hypertrophied, it was much easier to do the perineal operation than when the bladder was very atonic, over-distended, and without expulsive force. In such a case it was much safer, in his judgment, to have a suprapubic opening for the management of hemorrhage and bloodclot. The surgeon should not be wedded to any one surgical procedure in these cases.

Dr. E. W. Lee of New York said that before attempting to operate upon the prostate, a thorough examination of the interior of the bladder with the cystoscope should be made if possible. In his own experience, castration and vasectomy had positively reduced the size of the prostate, and he thought many of the objections that had been raised against these operations had been very largely founded on foolish sentiment. These old men were seldom in a condition to undergo the serious operation of prostectomy, and they could often be relieved by a simple suprapubic cystotomy with drainage.

Vesical Emergencies; Their Surgical Management.—Dr. Eugene Fuller of New York read this paper Speaking of urinary retention dependent upon swelling and inflammation, he said that if there were no prostatic obstruction and olivary-pointed catheters failed to pass, the small whalebone bougies should be tried. When a filiform bougie could not be made to pass, it was usually because of the presence of false passages or of secondary inflammatory changes causing disorganization of the parts. In the Gouley tynneled catheter, which slips over the fine guide, one had the means of giving such patients relief. Where prostatic obstruction was present, a large catheter could often be passed. Although the silver prostatic catheter could almost always be passed, it was a dangerous instrument unless very carefully used, and at the present time it should be looked upon solely as an emergency instrument.

Uterine Prolapse.—Dr. Frederick Holme Wiggin of New York presented a paper on this subject. He said that the causation of uterine prolapse was to be found in the separation of the muscles of the pelvic floor where they unite in the median line. The resulting malposition of the bowel was increased by lifting and by straining at stool. The descending uterus must necessarily take the bladder with it, and after a variable period of time, complete prolapse occurs. The treatment must necessarily consist of an operation which would obliterate the hernial sac and restore the damaged perineal structures as nearly as possible to their normal condition. The prolapse should be reduced and the patient kept in bed with the foot of the bed raised, and antiseptic tampons should be used. After local ulcerations had been healed, a laparotomy should be done, and a purse-string suture of kangaroo tendon should be passed through the fibers of the uterus, about at the attachment of the round ligament, and then through the broad ligament. The latter is thus folded up and its excessive length reduced, while the uterus is given a new point of attachment near the insertion of the broad ligament at the pelvic brim. The same procedure should be done on the other side. After this operation the patient is again placed at rest in bed. Four or five weeks later a second operation should be done for suture of the separated tendons of the perineal muscles. The author said that he had done this operation a number of times on aged women, and had found that it had been well borne. This was because it could be quickly done and without any great loss of blood. It was probable that intraspinal cocainization would prove of advantage in these operations on old people.

Typhoid Cholecystitis.—Dr. Charles G. Stockton of Buffalo presented this paper in conjunction with Dr. Albert T. Lytle of Buffalo. They reported four cases of cholecystitis complicating typhoid fever. The first case had apparently begun with cholecystitis; in the second case, it was doubtful whether it had begun in this way; in the third case, the cholecystitis had developed between the tenth and sixteenth days, and in the fourth case, on the nineteenth day. Typhoid bacilli had been frequently found in the gall-bladder, and it was apparent that the infection was often latent, or the cholecystitis was so mild as to escape observation. A marked leucocytosis might lead one to operate. In the first, second, and fourth cases, there had been considerable leucocytosis. In the first case, preparations had even been made for operation, but it had not been done because of sudden improvement. In many non-suppurative cases, there were chills, high fever, intense pain, and alarming prostration.

Dr. De Lancey Rochester of Buffalo said that in the case which Dr. Stockton had seen with him the urine had been regularly examined every third day. Finally, indicanuria had shown itself quite markedly. The next day the patient had had a slight chill, and the leucocyte count had been something over 11,000. The indicanuria had increased in proportion to the increase in the leucocytes. When the leucocytes had reached 22,500, the indicanuria had been exceedingly pronounced. The disappearance of the Ehrlich reaction before the cessation of the cholecystitis was also an interesting feature of the case.

Dr. Allen A. Jones of Buffalo said that cases had been reported in which the pain had been as severe as in biliary colic, yet at operation only a cystitis with a mucoid co!

lection had been found in the gall-bladder. On evacuating this, and draining there had been complete subsidence of the symptoms.

Dr. E. D. Ferguson of Troy said that it was undoubtedly true that it was the cholecystitis that caused the severe pain, and it did so in connection with the evacuation of the contents of the gall-bladder. The pain occurs in cases of cholecystitis regardless of the presence or absence of gallstones.

Dr. Stockton remarked, in closing, that he had introduced the subject of gallstones merely to emphasize the belief that the cystitis is really the starting point of the gallstones.

What Percentage of Gouty and Rheumatic Patients Develops Fatal Pulmonary Phthisis?—Dr. Thomas F. Reilly of New York endeavored by statistical studies to answer the above question. He said that during the past year he had questioned one hundred patients in St. Joseph's Hospital suffering from phthisis. Of this number there had been only six who had not had at some time in their lives an attack of acute articular rheumatism. In four other cases, there had been a family history of rheumatism. Not one of the whole series had ever suffered from gout or from diseases generally considered to be of gouty origin, nor had they a family history of gout. This inquiry had also shown a history of exposure, of prolonged alcoholic excesses, and of loss of sleep in 2 per cent. of the cases. Loss of sleep had been a prominent etiological factor in 45 per cent., and in most of the remainder phthisis had followed an attack of one of the infectious diseases. The patients were from the lower walks of life, and had been exposed a good deal to inclement weather and to those conditions which are apt to lead to alcoholic excess. Quotations were made from the literature bearing upon this subject in support of the views advanced. It was shown that many writers had commented on the absence in pulmonary tuberculosis of those cutaneous affections which are generally associated with the acid diathesis.

A Durham Tube in the Right Bronchus—Dr. E. D. Ferguson of Troy reported this case, which occurred in a person of forty-two. The fault in the silver tracheotomy tube swallowed lay in the absence of a collar to prevent the escape of the tube in case the set screw became worn and gave way. A modification was presented which was intended to remedy this defect and prevent the repetition of such accidents as the one reported.

Resection of the Cervical Sympathetic Nerve in the Treatment of Glaucoma; Its Present Status.—Dr. Wilbur B. Marple of New York read this paper. He said that as long ago as 1866 experiments had been made upon the sympathetic nerve of animals. As a result of these, it had been stated that the intraocular tension was diminished and that the eye became smaller. In 1897, Jonnesco had first removed the cervical sympathetic glands for glaucoma. Last year, reports of seventy-four operations, performed for this condition, had been collected in Germany, and Dr. Marple said that he had been able to collect thirteen more. This operation had only been suggested for chronic glaucoma, and the great defect of all the cases that had been reported was that they had been observed for too short a time to admit of drawing just conclusions. There could be no question that in many cases operated upon improvement had followed, but in some of them this improvement had not been permanent. We were not yet in a position to say in just what cases the operation is indicated, or what would be the ultimate result. His own view was that when a case of glaucoma had gone on to excavation of the optic nerve and rather pronounced optic-nerve atrophy, permanent improvement of vision was hardly possible. This operation does not replace iridectomy, but supplements it.

Dr. James J. Walsh of New York said that he had seen the ganglia that had been removed in Jonnesco's first case, and had heard him describe his work in 1897. Since that time, Jonnesco had done about 122 operations. In a series of his cases, done three years ago, there had been improvement in glaucomatous cases, especially in the irritative chronic type, and in one case of the hemorrhagic type. The vision had been doubled in one case, and this improvement had continued now for three years. In cases of exophthalmic goiter in which the exophthalmos was so great as to make the loss of the eye almost inevitable, Jonnesco had found that by the removal of the cervical sympathetic nerve so much improvement could be effected that the eye could be saved.

Dr. Alvin A. Hubbell of Buffalo said that he had never himself undertaken Jonnesco's operation, because it did not seem to him to promise very much, and it was certainly yet in the experimental stage.

Dr. Marple said that among ophthalmologists everywhere it had been a matter of regret that in Jonnesco's published cases the histories had been uniformly so meager and that the cases had not been watched for a longer time.

Report of a Case of Gunshot Wounds of the Intestines.—Dr. H. Van Hoevenberg of Kingston reported the case of a man of thirty-three years who had been shot in an altercation by another man who had been standing only five feet away at the time. The ball had penetrated the skin one inch to the left of the umbilicus, and had passed downward and to the right toward the iliac region, and had entered the abdominal cavity at the median line. He had not seen the patient until over three hours after the shooting, and had then urged operation, but had been unable to obtain the man's consent until six hours had elapsed since the injury. The surroundings were unfavorable for operation, but it had been undertaken nevertheless, the light being furnished by three kerosene lamps held by neighbors. Ten perforations of the intestine had been found, two in the ascending colon, and the others in the small intestine. Some fecal matter had escaped into the abdominal cavity. The operation lasted two hours. After several days, a persistent elevation of temperature had pointed to some complication, and it had been found that the ball was located under the posterior border of the right external oblique muscle. It was removed, and the abscess cavity cleansed with peroxide of hydrogen and packed with sterile gauze. From this time on recovery had been uneventful. No solid food had been given until the twelfth day. The speaker said he thought considerable importance should be attached to the use of morphine in these cases of perforating wound of the intestine in order to quiet the peristalsis. The case was reported to emphasize the fact that, no matter how discouraging the circumstances, it was the duty of the surgeon to give his patient a chance for life.

Dr. R. H. M. Dawbarn of New York said that he had long advocated this special use of morphine under the designation of "the morphine splint." When morphine was given in a case of gunshot wound of the bowel, the injury in the latter remained absolutely still, and no waves of faeces were thrown against the wound until it had a chance to become sealed up by fibrinous exudate. It is now known that the contents of the small intestine are fluid, while the contents of the large bowel are more or less solid. An autopsy on one case of this kind had demonstrated that such wounds might become tightly sealed in so short a time as two hours. At present, he did not recommend or make use of the interrupted suture in the bowel, because the introduction of this suture required from three to five times longer than the insertion of the continuous suture, a matter of no small importance in this field of surgery.

Indications for Treatment in Uterine Myomata.—Dr. George Tucker Harrison of New York presented this paper. In spite of the statements of many gynecologists to the contrary, he asserted that it was the rule

for uterine myomata to undergo retrograde degeneration after the menopause, the exceptions to this rule being quite rare. Thrombosis of the larger veins was not infrequently observed in women having uterine myomata, who suffer from hydræmia. As the hemorrhages associated with myomata were dependent upon endometritis, he urged every physician to make use of the curette before attempting more radical measures. Sometimes a complicating peritonitis afforded an indication for an operation. Where myomectomy is done, the vaginal route was to be preferred.

Technique and Method of Inserting the Fixation Sutures for Prolapsed Kidney.—Dr. AUGUSTIN H. GOELET of New York presented this subject. The object of the operation, he said, was to fix the kidney in its normal position to the muscles of the back. Non-absorbable sutures, such as silkworm gut, were to be preferred. The operation involved no risk *per se*. The incision is made along the outer border of the erector spinæ muscle, beginning just below the twelfth rib and extending downward parallel to the spine for about three inches. The incision passes through the skin and fat down to the superficial fascia covering the muscles. This fascia is then divided, and the underlying muscles down to the erector spinæ are separated with blunt hooks in the direction of their fibers, broad retractors being used to control the deeper muscles and the deep fascia. He did not think it was necessary to strip back the fibrous capsule of the kidney, in order to secure firm adhesion. Two fixation sutures are used, being inserted upon the lower half of the kidney in such a way that the traction comes at a right angle to the kidney surface. A suture inserted by this method bears at least five times as much strain as the ordinary transverse suture. It was the fibrous capsule, and not the kidney structure itself, which resists the strain. The suture used by him passes through all the structures of the back. At the suggestion of Dr. Howard Lilienthal, he had made use of strips of aseptic adhesive plaster in bringing the muscles of the back together.

Dr. GEORGE M. EDEBOHLS said that it had been invariably found that the union obtained by exposing the kidney substance was the stronger. The opening of the capsule was, moreover, an excellent procedure in itself, relieving as it did the tension so often present in a kidney that had been displaced, and allowing of the formation of new vascular connections. He had had several cases of movable kidney complicated by nephritis which had been permanently cured by this operation, and he would explain the good result by the new vascularization produced. A common error in operating for fixation of the kidney was to try to anchor that organ by its lower half only. In his own last series of one hundred cases he had dispensed with drainage. His method was to split the capsule proper from one pole to the other, and reflect the capsule so as to raw about one-half of the kidney surface. He then anchors the kidney by transfixing the capsule proper by four suspension sutures, one over the middle of each pole, front and back, and subsequently passing the sutures through the muscles, tying them in the subcutaneous fat and burying them there. The kidney is anchored to the rawed quadratus lumborum. It should be attached so that the middle of the kidney will be in the middle of the loin.

Dr. HOWARD LILIENTHAL of New York said that the method described in the paper was an exceedingly simple one, and certainly brought the kidney into better position than other methods. He thought all suture methods must fail if there were enough room for the kidney to be displaced downward. His aim was to fill up in bulk the place occupied by the displaced kidney, and to this end a large gauze packing should be left in for about ten days, or until it comes out with great ease. He had not seen any evil result from this procedure in a considerable number of cases. By this method granulation over a large surface was produced, and when these surfaces were in contact, the space into which the kidney might descend was obliterated, and, so far as he knew, remained so. He was of the opinion that the nephritis found in connection with displaced kidney was not a true nephritis, but merely the result of passive congestion, and on this theory it was easy to explain the good results observed by Dr. Edebohls by the improvement in the circulation of the part.

Dr. WILLY MEYER of New York said that this method of gauze packing had been first employed as long ago as 1893; but to accomplish the desired result, it seemed necessary to keep in the gauze for two weeks or longer. The originator of this method had kept in the gauze for three weeks and had then removed it under anæsthesia. If, however, the technique of Dr. Edebohls were observed, primary union should occur, and the patient should not have to remain in bed more than three weeks.

Dr. R. H. M. DAWBARN said that he believed with Dr. Senn that, with the exception of Dr. Edebohls, very few surgeons had obtained satisfactory results from nephropaxy. The methods of suture described seemed to him objectionable because they caused leakage of urine; hence, it seemed to him safer to use a Mikulicz drain inserted down to the capsule until all danger of leakage of this fluid had passed. As to the mode of fixation, he preferred the technique ordinarily described as that of Andrews.

Dr. GOELET, in closing, said that by his mode of inserting the sutures it was impossible to fix the kidney by its lower pole; the sutures are inserted into the lower half of the kidney, and not into its lower pole. He could not believe any leakage of urine took place, as described by the last speaker; certainly he had never observed it.

A Case Simulating Glanders.—Dr. J. R. STURTEVANT of Theresa reported this case, which was characterized by a peculiar eruption of blebs, as shown in the photographs presented.

ELEVENTH ANNUAL MEETING OF THE AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION.

Held in Buffalo, N. Y., September 24, 25, and 26, 1901.

ERNEST WENDE, M.D., OF BUFFALO, PRESIDENT.

First Day—Tuesday, September 24.

THE meeting was called to order by the President, Dr. ERNEST WENDE of Buffalo, in the Seventy-fourth Regiment Armory, Buffalo. The address of welcome was made by the Mayor, Dr. CONRAD DIEHL, and was responded to for the association by Dr. ROBERT NEWMAN of New York.

Address of the President.—Dr. ERNEST WENDE, in his address, dwelt upon the progress that had been made in his city in harnessing the power of Niagara. He said that one-fifth of the electrical power now used in Buffalo was furnished by the power of the great cataract. In April, 1894, the first power had been generated from this source, and its potentiality recognized. In November of the same year the Street Railway Company had brought one thousand horse power from Niagara to Buffalo, but it was not until November 22, 1898, that the current so obtained was used for lighting the streets, Main street being the first one illuminated in this way. A few months later it was in general use for lighting purposes. The speaker next considered the possibilities and limitations of electrotherapeutics. He referred to the Bottini operation as one holding out greater prospect of benefit to the prostatic sufferer with less attendant risk than any other. In chronic rheumatism, he said, currents of electricity of high frequency were most effective, and success was the rule if the treatment were persisted in. In conclusion brief reference was made to

electric light and x-ray therapy, to the cataphoric treatment of cancer, and to electrolysis in the treatment of urethral stricture.

Rectal Stricture Treated by Electrolysis.—Dr. W. H. White of Boston, Mass., read a paper on this subject, reporting a case. He said that the treatment was necessarily slow and required a careful cleansing of the parts. The case reported by him had been previously under the treatment of a rectal specialist for over one year, the method of dilatation having been employed. The stricture was three inches and a half from the anus. Owing to the great nervousness of the patient it had been necessary at first to make use of cocaine. The treatment had been given at intervals of about four days for a short time, and then had been suspended for about two months, while the patient had been out of the city. He had first used a copper electrode for the cathode, with a large pad on the back for the anode. It had required fifteen minutes to pass through the stricture. A No. 54 electrode had been used at the next sitting, and only ten minutes had been required to pass the stricture. Subsequently a zinc olivary electrode had been substituted, being used in connection with the anode. The treatment had been interrupted at times for various reasons, but in less than a year the stricture had been completely cured.

Neurasthenic Paralysis.—Dr. Francis B. Bishop of Washington, D. C., was the author of this communication. In it he considered more especially the highly strung nervous individuals who are living up to their full quota of nervous energy. They are usually poor sleepers, and do not fully recover from one day's work before they plunge into that of the next day. The inevitable result was collapse, but before this occurred it was common to observe hysterical spells or periods of despondency. An exceedingly severe case of this kind was then reported in which the only treatment employed had been electricity, together with the free use of water and methods for improving the general nutrition. The treatment had proved successful after about six months.

Dr. Massey thought the case reported was rather one of hysteria. The benefit resulting from the use of faradic and static electricity was worthy of note.

Dr. Robert Reyburn of Washington, D. C., thought it was often difficult to draw the line between hysteria and neurasthenia. Many practitioners of high repute were given to careless routine practice and a slavish use of drugs. Electricity was often useful by affording an efficient substitute for drugs.

Dr. W. B. Snow of New York said that in this class of cases it had been his custom to use static electricity, and he had yet to see the case that would not yield to such treatment. It was the duty of electrotherapeutists to impress upon neurologists and alienists the value of electrical treatment in the early stages of melancholia.

Dr. W. J. Morton said that he would unhesitatingly put down the case reported in the paper as one of hysteria and not of neurasthenia. While static electricity was useful and convenient in the class of cases under discussion, if it became necessary to treat the patient at his home one would be compelled, as Dr. Bishop had been, to use the galvanic current.

Dr. Bishop in closing said that he had never seen a true case of hysteria unassociated with nerve exhaustion or neurasthenia, and, on the other hand, he had never met with neurasthenia without some of the symptoms of hysteria. By the application of negative galvanism to the heart, the pneumogastric nerve was stimulated, and the heart given a chance to rest between the beats, and so to accumulate force. Moreover, the action of the galvanic current on the solar plexus and upon the brain was not to be forgotten.

Value of Electricity in the Gynecological Work of the General Practitioner. Dr. M. F. Wheatland of Newport was the author of this paper. Attention was chiefly directed to the value of electrotherapy in dysmenorrhœa, endometritis, subinvolution of the uterus, non-suppurative pelvic peritonitis and cellulitis, and in uterine fibromyomata. Three illustrative cases were reported.

A Modified Intrauterine Electrode for Cataphoresis.—Dr. Wheatland also presented and described a modified electrode for intrauterine cataphoresis. The modification consists in the adaptation of a syringe, so that the cotton, after its introduction into the uterus, could be saturated with the selected medicament.

Dr. G. Betton Massey was of the opinion that better results could be obtained from his method of mercuric cataphoresis in the vagina than by intrauterine cataphoresis. The electrode was connected with the positive pole, and the application pushed to the point of causing considerable discomfort by producing an erosion of the vagina.

Dr. O. S. Phelps of Battle Creek, Mich., said that he had found no occasion to resort to cataphoric intrauterine applications because metallic electrolysis had served him so well during the past ten years. Metallic electrolysis seemed to him to give all the possible advantages of cataphoresis with the least possible disadvantage; indeed, after an experience in gynecology of thirty years he felt free to assert that metallic electrolysis is far in advance of all other known methods of treating chronic endometritis. To use electricity successfully in gynecology, the physician must not only be a practical gynecologist, but must thoroughly understand electrophysics and electrotherapy.

Dr. Robert Reyburn spoke of his successful use of electricity in the treatment of fibroid tumors. He believed the use of the knife, especially in cases of cancer, had been a stupendous failure. He made use of a current strength of fifty to seventy-five milliamperes, and succeeded in effecting practical cures.

Dr. R. J. Nunn of Savannah remarked that the practice of injecting fluids into the uterus had been discarded because of the danger of forcing the fluid into the fallopian tubes, and this very reason seemed to him to constitute a serious objection to the use of the instrument just presented. It was a safe general rule in gynecology that if one must introduce a sound into an os so contracted that it would squeeze out the medicament on the cotton applicator, such a procedure was not safe. The remedy consisted in dilating the opening before making the intrauterine application.

Dr. Wheatland said that he had been led to devise this instrument because he had been using Skene's uterine pipette for four years. The electrode presented was intended to be used with the negative pole in stenosed conditions of the uterus. The tip of the instrument is made of block tin.

Second Day—Wednesday, September 25.

The Wave-Current Controversy Settled.—Dr. C. R. Dickson of Toronto, Canada, presented the report of the special committee appointed at the last annual meeting of the association to consider the wave current. The appointment of the committee arose out of a controversy between Dr. A. D. Rockwell and Dr. W. J. Morton regarding certain currents obtained from the static machine. The committee consisted of Dr. W. J. Herdman of Ann Arbor, chairman, Mr. A. E. Kennelly, and Mr. W. J. Jenks. The report presented was very exhaustive, and hence only a digest was read. The committee carefully avoided the question of priority among contemporary practitioners, but set itself the task of determining whether or not the undulatory current had been long prior to 1880 similarly produced, used and described by experimenters or physicians who are not now living. The report gave copious quotations from Dr. W. J. Morton's communications to various medical journals. Three diagrams, with references, were given to elucidate the subject. These diagrams are described in great detail,

and following these is a summary of Dr. Morton's claims for priority of the results attained by him in 1881, of the erroneous statements that had been made, and of the recent recognition of Dr. Morton's work, chiefly from foreign sources. The committee did not consider the precise character of the current material. The conclusions were as follows: (1) That the evidence before the committee indicates that in 1880, or thereabouts, Dr. W. J. Morton devised and used an arrangement of previously existing static electrical apparatus, and in its use practised a method of producing currents which had been widely adopted and recognized as useful in subsequent medical work; (2) That the arrangement and method had not heretofore been known or practised and were not evident to those skilled in the art as a result of their prior knowledge and experience; (3) That the claims of priority detailed by the committee as made by him are entitled to recognition by the association. An appendix to the report shows that no less than forty-six publications had been examined by the committee, and extracts are given in full relating to all the matters concerned, together with some diagrams and blue-prints taken from the books consulted. This report of the committee was accepted by the association, and ordered published.

A New Transformer.—Dr. S. F. Wilson of Montreal, Canada, exhibited an instrument built on the induction-coil plan, and presented with it a description furnished by the makers of the instrument. It was claimed by the makers that it did not heat and that it made very little noise.

Effects of Electro-Static Modalities upon Hyperæmia and Pain.—Dr. William B. Snow of New York read this paper. The author stated that these modalities remove stasis, cause absorption of exudates, thereby lessening pain and swelling, promote the reabsorption of organic and inorganic salts which have become locked up in the tissues as a result of defective metabolism, produce a general equalization of the blood currents to all parts of the body, with decided lessening of the arterial tension, and thus diminish congestion and promote regeneration and restitution of the parts to the normal. In cases of surgical œdema, great satisfaction would be derived from static treatment, and the same general action would be observed in many other varieties of passive hyperæmia. Prolonged administration of the brush discharge or spray produced a marked rubefacient effect. If the applications were made sufficiently often, pain would be permanently relieved. There was no class of inflammatory affections which so tax professional skill as joint inflammations, and many of the most stubborn of these could be promptly cured by electrical treatment. Of 200 cases so treated, at least nine-tenths had proved failures under other modes of treatment. When ankylosis had not taken place and the joint structures had not been affected, the inflammatory process could always be stopped, most of the products of inflammation removed, and the joint made painless and useful. Sciatica, brachial neuritis, and all other uncomplicated cases of neuritis were promptly cured, and this was accomplished in a much more satisfactory way than by any other means. Inflammatory glandular affections yield remarkably good results. He believed there was no local application for eczema so effective as the brush discharge. It was essential to have the best modern static machine, having at least eight revolving plates, thirty inches in diameter, and capable of producing 300 revolutions per minute. The insulated platform should have glass legs, at least eight inches long. The wave current was rarely contra-indicated in cases of pain or hyperæmia, and was an important part of almost all treatment of chronic cases. The brush discharge was invaluable in the treatment of skin affections. It was successful in many acute affections in which a rubefacient was indicated. It was also useful in connection with the treatment of muscles which contract painfully. The spray was a substitute for the brush discharge, but was in no way equal to it. The administration must be continued until there was distinct sedation and reduction of hyperæmia. The treatment should be repeated before the pain had returned.

Dr. W. J. Morton emphasized the statement made in the paper that this proposed extension of electrical treatment into the domain of acute inflammatory diseases constituted the triumph of modern electrotherapeutics. A great deal of his own work had been in acute cases, e. g. in acute rheumatism or gout, in acute sprain, or, in fact, in any acute inflammatory structural alteration. This extension of electrotherapy would not have been possible with the galvanic or faradic currents.

Dr. O. S. Phelps of Battle Creek, Mich., said that as long ago as 1804 he had reported to this association a case of pelvic inflammation, associated with uterine fibroids, that he had successfully treated by electricity, thus proving that the treatment of acute conditions by electricity was not a new thing.

Dr. Francis B. Bishop of Washington, D. C., said that too much stress should not be laid upon the use of static electricity to the exclusion of the galvanic current, particularly as the latter alone was within the reach of many practitioners in country practice. When properly used, the capabilities of the galvanic current were very great. While the large modern static machines gave certain useful effects, it should be borne in mind that certain results were obtainable with the smaller machines that were not within the range of the larger ones. For example, in extreme cases of neuritis he had found that the fine vibratory current of the small static machine was very soothing, while that from the larger machine could not be tolerated. The current he referred to was not, however, the Morton current, but that obtained from one side only, and yielding very fine vibrations. The static sparks he had not used in acute affections for a number of years, chiefly because the treatment was so painful. In subacute inflammation, as, for example, sciatica, he had found galvanic electricity decidedly preferable to static.

Dr. J. D. Gibson of Birmingham, Ala., said that he had used the galvanic current with marked success in some cases of rheumatism, but it had not been nearly so useful as the Morton wave-current. In certain cases of sciatica and in rather obscure neuralgias of the lumbar region, static electricity had disappointed him.

Dr. G. Betton Massey raised the question as to whether it was wise to attempt to treat acute rheumatism by the use of static electricity, basing his remarks on a personal experience with several cases which had been distinctly aggravated by such treatment.

Dr. C. O. Files of Portland, Me., made the point that there were certain cases in which the spark could not be used and the spray was inefficient which could be successfully treated by the use of the static massage roller. By this means, he had succeeded in treating scores of cases of acute rheumatism, giving prompt and complete relief. It was necessary, however, carefully to graduate the strength of the current when applied with this roller. In warm weather, there was so much moisture in the clothing that it was not possible to convey any sensation to the patient on an insulated platform by the use of this roller. He did not use the insulated platform, but allowed the patient to sit on a chair on the floor, and used the negative pole of the static machine either connected with the gas fixture, or if this were too strong, the chain was allowed to remain upon the pole itself. Then by using some dry woolen material, such as a shawl, and varying the number of folds, the strength of the current could be accurately adapted to the requirements of the most sensitive or the most phlegmatic patient. He felt abso-

lutely sure that Dr Snow's statement concerning the electrical treatment of acute diseases would stand the test of time

Dr Morton remarked that when it was desired to give constitutional treatment with the wave-current, some point must be selected for the application of the electrode He had formerly chosen the spine for this purpose; but, because of the immense muscle masses in this region, had more recently made use of a plate of block tin, measuring four by five inches, placed at the beginning of the sternum, and had found this site particularly satisfactory

Dr Snow closed the discussion. He said that there was a marked difference between a spray and a brush discharge. For the latter, he made use of wooden electrodes, and kept them moist, but not wet When the application was made in this way, there was a singular difference between the currents of negative and positive insulation. The positive was associated with a number of green rays, even when the wooden electrode was used, and its effect was that of an irritant. The sedative action was obtained with the negative current. The machine should always be run at high speed In his experience, this method of treatment had never failed to relieve cases of acute rheumatism; but it was important that the interval between treatments should not be more than twenty-four hours.

Morton's Wave-Currents of the Static Machine and Werber's Insulator.—Dr. Robert Newman of New York presented a paper with this title. The author said that Morton called his wave-current the "electrostatic current." It was commonly applied by connecting the positive pole with the platform and grounding the negative, at the same time bringing the discharge rods into action. The working current leaked off from the prime conductor, and was applied directly to the skin by means of an electrode held in firm opposition. The remainder of the current was discharged across the spark gap, each spark causing an interruption or wave. In this way, the working current manifested itself in oscillations, and the effect was more or less localized in that the action was exerted more vigorously in the immediate area to which the electrode is applied to the skin. Dr. Snow had increased the number of electrodes, both directly and indirectly, and had made use of a Leyden jar having no direct connection with the prime conductor of the machine. The speaker said that Dr Gustavus Werber of Washington, D. C., had called his attention more than a year ago to a further modification of the wave-current ,Reasoning from analogy that a further compression of the current would give an increased leverage, so to speak, in influencing the tissues, Dr. Werber had devised an insulated terminal for one of the sliding poles of the machine. The device consists in the interposition of a section of vulcanite in the discharge rod to which it is attached By making this insulation sufficiently long to prevent sparking across under all circumstances, the power of compression of the current was limited only by the capacity of the machine, and the whole output of the current was forced into the patient at the point of contact, and being diffused through the intervening tissues was re-collected by means of a second electrode held in firm opposition with the skin. From here it was reconducted to the distal extremity of the discharge rod or beyond the insulating section, and was discharged thence in sparks through the opposite pole to the ground The length of the spark-gap regulated the compression to which the current was subjected. The inventor made the following claims for his modification of the wave-current (1) That the entire current of the machine is utilized as a working current instead of a small fractional part of it, as in Morton's use of it; (2) That all the current is caused to pass through that part of the body or other object interposed between the electrodes delivering and re-collecting the current to be dissipated by sparks and before the interruptions are made, (3) That the voltage and electromotive force of the working current are, therefore, much greater, thus increasing the effectiveness of the machine, or, in other words, enabling one to make a satisfactory use of a smaller static machine ; (4) That the tonic and alterative effects are exerted most vigorously at the point of exit from the body under the return electrode instead of at the point of entrance; (5) That this interrupted current is under perfect control, and can be made to pass from the center to the periphery, or in any direction; (6) That, using the whole volume with increased electromotive force, the current will produce better results with a number less of séances and of shorter duration. Dr. Newman added that he had made use of this modification of the wave-current almost daily for many months, and had been able to substantiate some of these claims. He had been able, for example, to accomplish in ten minutes with the same results which had formerly required thirty minutes. The larger the ball the greater the compression, but the fewer the waves or interpolar interruptions. He believed that the smaller balls and the more rapid waves would be found to give the best results, and that the high frequency current with rapid vibrations would more quickly restore health and tone to diseased tissues.

Dr. W. J. Morton, in opening the discussion of this paper, remarked that he believed the entire printed literature on this subject comprised a description of a patent taken out by Dr Werber. The great beauty of the ordinary method of administering the wave-current was that the patient received the entire discharge, so that a general as well as a local effect was secured. At the last meeting of the association he had described and exhibited a zinc screen, called an insulating capacity, by means of which the current could be concentrated at two points. The insulated ball in the Werber modification was, for all practical purposes, nothing more than such an insulated capacity, though more convenient. The insulated ball was really a ground chain to the circuit gap.

Dr. W. B Snow said that he had been using a modification of this idea all summer, and had found it very useful for obtaining local effects, particularly when, because of humid weather, a long spark-gap could not be obtained in the usual way. However, there was one drawback to this plan, *i. e.* the external capacity being always the same, one could not vary the vibratory effect on the electrode connected with the ball. The other electrode would always be the stronger, and the special effect produced would be dependent upon the particular machine used. With a plate under the foot and another on the patient's back, and with the chair insulated by means of ordinary telegraph insulators, one could readily obtain Dr. Morton's "external capacity" described a year ago.

Dr. Gustavus Werber of Washington, D. C., said that his modification merely served to increase the electromotive force of the machine, and he had been led to devise it because he was desirous of materially reducing the duration of the long séances made necessary when the ordinary wave-current was used.

Ozone in Tuberculosis.—Dr. J. D. Gibson of Birmingham, Ala., in this paper described his experience with ozone generated by a static machine, and used in connection with medicated nebulæ. Cases were cited to show the good results of this treatment

Dr. C O. Files corroborated the statements made in the paper, and expressed the belief that all cases of tuberculosis in the first stage and early part of the second stage could be benefited by the ozone treatment.

Dr T. F Pease was of the opinion that perhaps one-third of the cases could be cured if taken in time, and treated in the manner described

Dr. W. J Ozone said that some years ago he had experimented in this field, but had been troubled with the simultaneous production with the ozone of a very irritating gas—nitrous acid. This he has removed by passing the impure ozone through a solution of caustic potash or soda.

The ozone, when thus purified, was found to be very agreeable to inhale.

Electric Lighting at the Pan-American Exposition.—Mr. HENRY RUSTIN, Chief of the Mechanical and Electrical Bureau of the Exposition, gave an interesting discourse on the electrical features of the Exposition. It was delivered in the amphitheater of the New York State Building. Mr. Rustin described the most popular electrical feature, the nightly build-up of the lights from no candle power to full candle power as follows: A rheostat, consisting of a tank of water, is used for this purpose. A large cast-iron knife, shaped quite similar to a very much-worn butchers' knife, is hung on a hinge, and has near the handle a projection or heel which never leaves the water. This knife is controlled by a rope actuated by a motor. At the time of the nightly build-up, all the lights are shut off for about two minutes, and all of the current from Niagara Falls used in the Exposition for lighting is made to pass through the water of the rheostat. The motor having been set in operation, the knife gradually sinks into the water, producing a greater area and less resistance, and finally the lamps are given the full candle power by the knife coming down into the contact points in the rheostat. Under the conditions found in this part of the country, the distance of Niagara Falls from Buffalo, twenty-four miles, is practically the limit that electric power can be economically transmitted: the distribution depends largely upon what insulation is practicable in a given climate. The present line wire is made of aluminum. The transformer losses are more important than the actual line loss under the prevailing pressure of 22,000 volts. This is the voltage on the line as far as the outskirts of the city. There it is reduced to 11,000, and on the Exposition grounds is dropped to 1,800 before being distributed. At the lamps it is finally dropped to 104 volts.

The Electrical Treatment of Neuritis.—Dr. FREDERIC H. MORSE of Melrose, Mass., read a paper on this subject. The treatment, he said, depended upon the cause and the stage of the disease. Most writers object to the use of electricity in the acute stage, but with care and gentleness and the use of a very mild galvanic current and a very large stationary electrode gratifying results could be obtained. In cases of long standing, when the pathological condition was one of interstitial fibrous change, our object should be to improve the nutrition of the part. The faradic brush and coarse coil with slow interruption and the interrupted galvanic current would benefit many cases when the high-tension current would be of no avail. In old and debilitated subjects, the séance should be repeated at short intervals. In the use of galvanism on an inflamed nerve, great care must be observed to avoid shock.

Dr. W. J. MORTON said that he had had an extensive experience in the electrical treatment of neuritis, and as long ago as 1892 he had published some radical views on this subject. At that time he had advised that, no matter how acute and painful the neuritis, sparks should be directly applied to the painful area for ten to twenty minutes daily. He looked upon this mode of treating neuritis as surely a specific as the use of quinine in malaria. While he had treated many of these cases recently with the new wave-current, his preference was still for the long, clean spark, reserving the wave-current for those persons who would not submit to the severer treatment. He had had a very large percentage of cures, and the average period of treatment had been quite short—from four to six weeks. The method of resting the painful parts in splints or plaster bandages was not free from danger, as 8 or 10 per cent. of these cases had developed ankylosis of important joints.

Dr. G. BETTON MASSEY also spoke against the rest-cure treatment of neuritis. He considered the treatment of acute neuritis of the sciatic still an unsolved problem. For the chronic cases, the static spark or the static breeze was useful, but for the bedridden cases he would recommend the faithful trial of the high-tension faradic current.

Dr. W. B. SNOW spoke enthusiastically of the results he had achieved in the electrical treatment of neuritis. He made use of static electricity, and usually found no difficulty in continuing a course of this treatment if he could have the severe and helpless cases only carried to the office once or twice. For the first few days he often gave the treatment twice a day, and after that once daily. If a relapse took place between two treatments, it was an indication that the interval between the séances had been too long. The treatments with the wave-current were necessarily long, for the treatment should be continued until the patient could leave the office free from pain.

Dr. F. B. BISHOP insisted that the galvanic current was useful in both acute and chronic neuritis, and could be used with just as good effect as static electricity, though perhaps less conveniently. His method was to use electrodes having very large surface, and directed the current through the course of the nerve, putting the positive pole, in a case of sciatica, over the painful area of the hip and the other electrode at the popliteal space. The current strength was very gradually increased to fifty or seventy-five milliamperes, and was kept at this point for half an hour. In nine cases out of ten, the patient would be relieved, and would remain free from suffering longer than where the static machine was used. He had never been able to secure a fine enough vibration from the Morton wave-current for these sensitive patients. The current he used was obtained by taking the ground from the opposite pole, and getting the induction through the air. The treatment advocated by Dr. Morton was certainly very severe, and while not doubting the results attained with it, it was a method that did not appeal to his judgment.

Dr. JOHN GERIN of Auburn, N. Y., bore testimony to the value of treatment with static sparks, and said that his experience with the use of the galvanic current in cases of sciatica had been that it tended to aggravate the trouble.

Dr. T. F. PEASE reported a severe and long-standing case of sciatica that had been promptly cured by static electricity after many other methods of treatment had completely failed.

Dr. J. D. GIBSON said that he knew of nothing equal to static electricity with the use of sparks for the treatment of uncomplicated neuritis. The relief afforded by the galvanic current he had found to be very transient. In both acute and chronic sciatica he preferred the long, heavy spark.

Dr. JOSEPHINE G. DAVIS of New York said that she had been very successful in the use of the high-tension faradic current in the treatment of sciatica.

Dr. MORSE in closing said that he had recommended several modes of treatment, because all patients in private practice would not submit to the treatment advocated by Dr. Morton, even though it were the best. He had never dared to make use of the very strong galvanic currents advised by Dr. F. B. Bishop.

Why I Use Electricity in General Practice.—Dr. S. W. BAYLISS of Buffalo read a paper with this title, and illustrated his remarks with lantern views. The chief topic considered was *x*-ray photography.

The Cause and Prevention of Common Errors in Radiography.—Dr. L. A. WEIGEL of Rochester read this paper. He said that the more common errors were the following: (1) General distortion from improper relation between the object photographed and the source of illumination; (2) Improper exposure; (3) Imperfect development of the photographic plate; (4) Chemical defects in the plates themselves; (5) Failure to make two plates at right angles to each other to verify certain observations; (6) Ignorance of *x*-ray anatomy, especially regarding epiphyseal

lines in young subjects. (7) The superposition of various planes; (8) Movement of the subject, producing a blurring of the image, and last and most important of all the use of the fluoroscope. Until some standard for posture had been adopted, the radiographs by different operators could not be properly compared. He would defy any one to present a case of fracture that could not be demonstrated by the *x*-ray. Of course, if only one radiograph were made, the fracture might elude observation. The difficulty arising from the superposition of various planes could be overcome by the use of the stereoscope. By means of this instrument even those unskilled in examining radiographs could often correctly interpret them. Another valuable feature of the stereoscope was that it absolutely reproduces the posture of the part at the time the radiographs were made. He was positive that the fluoroscope was responsible for more errors in connection with *x*-ray work than any other one thing.

Third Day—Thursday, September 26.

The Case of Mrs. D——. A Study in Contemporary Gynecology.—Dr. G. Betton Massey of Philadelphia reported this case with the object of pointing out, among other things, the danger of forcible dilatation of the cervix, and to show the unfortunate tendency of modern gynecology to mutilate women.

Drs. Robert Reyburn, S. W. Bayliss, O. S. Phelps, J. D. Gibson, and R. J. Nunn discussed the paper, and in doing so commented strongly on the present tendency to resort hastily to mutilating operations with sad and far-reaching consequences, whereas in many painful, non-suppurative conditions in the female pelvis better results could be obtained by the skilful use of electricity.

Easy Method of Testing the Strength of the Galvanic Current.—Dr. Robert Reyburn of Washington, D. C., presented this communication. The author said that he had found the ordinary milliamperemeter not sufficiently portable for use in country practice, and he had consequently experimented with an ordinary galvanometer, and had found that it could be used in emergencies with very good result. A table was presented showing the results of the tests he had made with this instrument up to 150 milliamperes. By a similar series of observations each practitioner could calibrate the particular galvanometer which he uses.

Report of the Committee on the Rontgen Ray.—Dr. Charles O. Files of Portland, Me., as chairman, submitted this report. He said that he had done a great deal of *x*-ray work, and had learned that it was not the size but rather the number of plates that constituted an important factor in such work. One of the members, Mr. E. E. Kinraide of Boston had recently brought out a coil machine which enabled the exposure to be greatly reduced. This coil was constructed on an entirely new principle, and gave a spark of remarkable intensity.

Mr. E. E. Kinraide of Boston said that his object in constructing this coil was to remove the high potential region of the coil as far as possible from the primary, and so remove the danger of destroying the coil so common to the ordinary Ritchie coil. The primary is placed on the outside, so that the lines of force fall away from the primary toward the center, and produce a very high potential there, while there is little or no potential at the outer turns. There is practically no tendency for such a coil to break down. The primary is operated by a form of spark-gap, the efficiency of which is due to a low potential current discharging across a very small air space and producing erosion of copper plates, thus interrupting the primary circuit. The condenser has about 900 volts, and discharges between two copper plates, about six inches in diameter and about $\frac{1}{100}$ of an inch apart. The air-gap is regulated by a lever. In the device used for charging the condenser there is a rotary brake, making about 125 interruptions per minute. With each interruption here, there are from twenty to twenty-five interruptions in the primary circuit of the induction coils, thus giving about 5,000 interruptions a second. It is largely owing to this high frequency that the exposure of the photographic plate can be materially reduced. For the same reason it is probable that the current from this machine will find important uses in electrotherapy. The current is almost identical with that from the Ritchie coil except that it has greater frequency. The Tesla coil gives rather an alternating current.

Officers Elected.—*President*, Dr. Frederic H. Morse of Melrose, Mass.; *First Vice-President*, Dr. Daniel R. Brower of Chicago; *Second Vice-President*, Dr. Alfred T. Livingston of Jamestown, N. Y.; *Treasurer*, Dr. R. J. Nunn of Savannah; *Secretary*, Dr. George E. Bill of Harrisburg.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, October 1, 1901.

Joseph Collins, M.D., President.

Contribution to the Study of Spinal Fracture, with Special Reference to the Question of Operative Interference.—Dr. George L. Walton of Boston presented a paper on this subject, dwelling particularly on the question of whether it was not desirable to make early operation in this class of cases the common custom. The author said that there were no symptoms which would lead one to assert that the cord was or was not unquestionably crushed. In the case of so-called complete injury, one finds immediate relaxed motor paralysis and entire absence of rigidity or other irritative sign in the motor sphere. Partial injury to the cord might be indicated by slower onset of paralysis, its unilateral or irregular distribution, the partial retention of the reflexes, and subsequent improvement. In fracture with total transverse lesion the area of anæsthesia was generally sharply marked, and the level was materially below the seat of the lesion. The classical symptoms of complete transverse lesion certainly do not indicate conditions beyond repair. Incomplete anæsthesia points to incomplete lesion of the cord; the same is generally true of anæsthesia of limited or unilateral distribution. Injury to the nerve roots alone sometimes appears in the cervical region after stretching and bruising, perhaps with temporary displacement of vertebræ. The diagnosis of local concussion of the spine was still applied by certain authors to such cases. Retention of urine was the rule in all varieties of spinal fracture with injury to the cord, whether the lesion involved the cervical, dorsal, or lumbar cord. This probably showed that mechanical conditions prevent the escape of urine so long as the propulsive force is lacking. The symptoms referable to vasomotor disturbances are evasive and baffling. The usual rise of surface temperature might perhaps be explained by the dilatation of superficial blood-vessels due to the cutting off of the vasoconstrictor influence from the medulla. The absence of sweating tends to fortify the theory that the principal sweat center lies in the medulla, the fibers being interrupted in their course by the lesion. Sweat secretion appears to be due to specific nerve influence conducted by specific nerve fibers, and not to heat. It was now generally recognized that the knee-jerk is lost in cases of complete destruction of the cord, and cases of spinal fracture constitute no exception to this rule. The superficial reflexes were generally lost or diminished in these cases, and were probably always lost in the complete lesions. The Babinski reflex was a common later phenomenon, but he would doubt its occurrence in cases of total destruction of the cord without reparative processes. The local signs, such as the formation of a knuckle, were very variable, and not of much significance. Operation often shows that the apparent irregularity is of no importance. It should be remembered that a great variety of curves are found in the back in healthy persons free from injury. This statement was

fortified by the exhibition of a series of tracing from the backs of healthy students in the Boston Normal School of Gymnastics. The Rontgen rays might prove of value in making the diagnosis, but in his own experience this method had not yielded satisfactory results. The prognosis in cervical cases without operation was generally grave, death usually occurring within a few days. In cases of fracture of the dorsal or lumbar region without operation the prognosis was better, but still very grave. The fatality in non-operative cases was about 80 per cent. The statistics at hand were not very reliable regarding operative cases, because many unsuccessful cases were not reported. The cases operated upon at the Massachusetts General Hospital since 1870 yielded a mortality of about 64 per cent. In some quarters laminectomy was not advocated, but was even denounced. Apprehension regarding the danger of the operation had been entirely allayed, and many cases had been reported showing that laminectomy is not dangerous by reason of the weakening of the spinal column. It was doubtless true that in most cases the crush of the cord had taken place. The author was inclined to think that, owing to the decided limitations of our diagnostic ability, it was well promptly to resort to operation in all cases except the moribund and those with great displacement, and give the patient the benefit of the doubt. According to his personal experience, the course of the operative cases coming under his observation had been more favorable than he should have expected without operation from his previous experience and his knowledge of the literature. The neurologist was often asked whether it was wise to open the dura at the operation, and his answer should be in the affirmative. An œdematous condition of the arachnoid was apt to exist, and would be relieved by such a procedure; but the chief reason was the opportunity this afforded for inspecting the cord. Of late, the custom had been not to suture the wound, but to leave it open. It had been the usual custom in the past to secure drainage for a day or two, but various recent operators had demonstrated that it was not at all necessary, and by eliminating drainage one could secure quicker healing and greater immunity from sepsis. In cases of grave shock, it would seem to be reasonable to delay operation if only better to interpret the symptoms. Rapidity of operation was important, and the surgeon need not fear injuring the cord by the use of forceps.

Dr. Charles L. Dana said that his own experience had led him to believe that the operation is practically safe, and that the spinal column itself is not injured by the operation. He had not had any fatal results in his operative cases, about half a dozen in all, and two of them were cases of injury in the cervical region. It was a matter of astonishment to him that such long and severe operations could be done upon these patients without sacrifice of life. He must confess, however, that the ultimate results of these operations had not been satisfactory, according to his observation. He had seen some improvement in motion and in the bladder symptoms in these cases; but that had been about all, and it was quite possible that such improvement would have occurred without operation. If by clinical observation one could be sure that the cord was crushed, one should not recommend operation. This could often be done. If there was a line of anæsthesia coinciding with the line of paralysis, and this coexisted with the absence of knee-jerks, he would feel almost positive that the spinal cord had been cut across, although there were certain exceptional cases affecting the cervical region which did not seem to follow this rule. It seemed to him that the operation performed by Lloyd, and which the speaker had seen employed by Abbé, was the quickest, safest, and most effective. The author had done a service in bringing up this subject, and urging a more persistent effort to relieve this distressing class of cases. The general opinion among surgeons was that this was a class of cases which hold out but little hope of benefit from operation.

Dr. Edward D. Fisher said that he had had a number of cases of fracture of the spine under his observation, and in the main he would agree with the reader of the paper that an operation is advisable. He would do this because death rarely occurs as the direct result of the operation. Where there had been a fatal termination, he felt that the same result would have occurred if there had been no operation. In two cases that had been under his observation in which cocaine had been used, the operation had been done as well as under general anæsthesia. In one of the cases the injury had followed a dive in shallow water, and in the other from an acrobat diving off the shoulders of another acrobat. The lesions had been about the same in each case, and because of the situation of the lesion they had been afraid to administer a general anæsthetic. When the cord was touched there was a sensation of pain, but no localization, and the operation was conducted without any more shock than with general anæsthesia. He agreed with the reader of the paper that it was almost impossible to make an accurate diagnosis between cases in which the cord had been partially or completely crushed. He did not believe that a lesion through the cervical region with an absolute loss of reflex, positively indicated that there had been a complete destruction of that region. Sometimes, on cutting down and exposing the cord, one observed very little change in the appearance of the cord until the dura had been cut. Even then there might be very little change because of a hemorrhage in the substance of the cord. The distribution of the sensation in almost all of these cases was irregular, so that the classical picture was rarely observed. In many cases where there had been absolute loss of reflexes there had been partial recovery; indeed, in his experience it had been the rule to see only partial recovery.

Dr. Graeme M. Hammond did not think it was always possible for the neurologist to say that the symptoms presented were positively indicative of complete destruction of the cord. In one case, coming under his observation, in which a young man had fractured his fourth cervical vertebra by diving in shallow water, there had been evidence of complete injury to the cord. He had been operated upon a year or two afterward, but it was needless to say there had been no resultant improvement. In another case, in which there had been an incomplete injury to the cord, and in which operation had been resorted to shortly afterward, there had been complete recovery, and the man had returned to his occupation of wrestler. Within a few days he had seen a very interesting case. It had been first reported four years ago. Several bales had struck him on the back, and almost immediately he had presented the symptoms of tabes, pure and simple. He had had no reflexes, and almost complete anæthesia with the Romberg symptom. He had been operated upon twelve weeks after the injury, and had made a complete recovery with a return of reflexes. He had seen this man within a few days, now twelve years after the injury, and he had then presented absolutely no symptom of injury to the cord. Such cases naturally lead one to be rather optimistic in regard to the mild cases. The fact that there was spinal deformity meant nothing, for in Pott's disease of the spine there was often very marked deformity without any spinal-cord symptoms. If the symptoms presented in a given case pointed to the total transverse lesion of the cord, there was nothing to be done but to operate, and even this gave a forlorn prognosis. In the milder cases, the operation should be undertaken as soon as possible, as here the prognosis was much better. He would operate in any case, no matter how hopeless it seemed, because nothing else could be done, and the patient was no worse

off than before. In the milder cases it was our duty to operate.

Dr. B. Sachs said that the question arising regarding operative interference in these cases was similar to the question of surgical interference in Pott's disease or in cases of tumor. The answer to this question must depend very largely upon the stage. He could not agree with Dr. Hammond that operation should be done because, to say the least, the person would be no worse. It was still the fashion to delay surgical interference until everything else had been tried, whereas if surgical interference was to do any good, it should be practised at once. In cases of fracture of the spine, therefore, whether complete or incomplete, operative interference at the earliest stage could do no harm and might be productive of a great deal of good. The differential diagnosis between complete and incomplete crush was difficult. When the crush was complete, the reflexes were almost invariably absent, whereas if there was more or less maintenance of conduction through the cord, the reflexes were apt to be impaired or exaggerated according to the site of the lesion. The dissociation of sensation was, in his opinion, an exceedingly valuable symptom, as it pointed out the rather moderate involvement of the cord. He was inclined to think that it was often a root symptom, and not an indication of absolute involvement of the cord itself.

Dr. J. Arthur Booth said that his experience had been limited, but he had not seen any great benefit from operation, although it should be said that operative interference had been resorted to at a late stage. It seemed rational to treat fractures of the vertebræ on the same general surgical principles as fractures in other parts of the body. In two of his cases, the complete paraplegia existing prior to operation had remained unaffected, though there had been some diminution of anæsthesia and improvement in the condition of the bladder.

Dr. Joseph Fraenkel referred to a case at the Montefiore Hospital of fracture of the spine. The patient had been admitted a year and a half after the accident, and had been walking around since the injury. Although the operation had been done late, it was worthy of note that three years and a half after the injury the autopsy showed that the cord had not been entirely destroyed. About six years ago, he had presented to this society a paper on the differential diagnosis between complete and partial destruction of the cord. In four cases in which the reflexes had been lost, the autopsy had shown complete destruction in only one of the cases. That shock alone was sufficient to destroy the reflexes was an old physiological dogma. He wished to insist that it was important to note the condition of the deep and superficial reflexes, because for the maintenance of the deep reflexes it was necessary that the cord be intact, whereas this was not requisite for the superficial reflexes. The plantar reflex was the one that was not destroyed.

Dr. George E. Brewer said that there was a greater inclination in Boston than in New York for operating upon these cases. He had personally passed through various stages of opinion regarding operating on these cases. At first he had been influenced by those around him in Boston. The general rule had been when there was paralysis below the point of injury and involvement of the sphincters to do an exploratory operation. He could not recall a single one of these cases that had been benefited by the operation, though he felt that they had all been examples of complete crush of the cord. In New York City, the surgeons had been perhaps a little too conservative. Injury in these cases is either a crushing one, or there is a hemorrhage within or without the cord; hence the outlook from operation was not good. The cases of hæmatomyelia recover without operation; cases of severe crushing injury, even with operation, do not. This seemed to be the prevailing view here at the present time. Possibly some of the early successes were in cases of unrecognized hæmatomyelia, in which, of course, recovery would have taken place entirely independently of the operation. Last winter he had seen a girl with injury of the last lumbar vertebra. There was a sensory paralysis and complete loss of control of the bladder and rectum. Dr. Hammond had examined the case, and believing that there was no transverse lesion, had urged operation. The speaker had performed laminectomy, and had found only a small spicule of the bone. The patient had recovered from the operation, and at the end of six weeks had regained control of the bladder and rectum. When seen two or three months after operation, she had almost completely recovered. Had it not been for the advice of Dr. Hammond, he would have looked upon this case as an improper one for operation. It had been his practice to introduce in these cases a very small rubber dram.

Dr. A. C. Bruce of Brooklyn said that he had seen quite a number of these cases. In the past six months he had had several x-ray photographs made, and they had been so variously interpreted by those who had seen them that they had ceased to have any value. A case was mentioned in which great improvement had followed the removal of a spicule of bone in a man brought into the Kings County Hospital after a fall. A diagnosis had been made of fracture of the arch. An immediate operation had been done, and the arch found to be broken down, but this was not pressing upon the cord, but on a fragment of the tenth dorsal vertebra. This case had impressed him with the value of operative interference as a means of diagnosis.

Dr. Joseph Collins said that he had only seen a few cases of fracture of the spine, and these at a remote date from the injury. The future of spinal surgery for broken back, he affirmed, lay entirely in the hands of the neurologists—in other words, upon the diagnosis. This had been clearly brought out in the cases cited by some of the speakers.

Dr. Walton, in closing, said that the statement made by Dr. Dana regarding the symptomatology of complete crush of the cord seemed to impeach the testimonies of a number of trustworthy observers. Regarding late operations, he would say that if the pressure had been removed there was no use in operating, and if the pressure had existed for many months there was little prospect of doing any good by operating. Theoretically, the late operation would be useful in cases in which symptoms arose from the formation of callus on the inside of the laminæ and the pressure on the cord, but his personal experience did not include any case of this kind. Instead of picking out an occasional case for operation, he would advise selecting one in which an operation should not be done—in other words, a case which was in great shock and practically moribund.

MANHATTAN DERMATOLOGICAL SOCIETY.

A regular meeting was held on Friday evening, October 4, 1901, at the residence of Dr. I. P. Oberndorfer, 1037 Lexington Avenue, with Dr. Wm. S. Gottheil in the chair.

Favus Corporis.—Dr. Gottheil presented a child of seven months with three typical patches in the interscapular region. No subjective symptoms existed. No history of infection was elicited, and the general health was good. The disease had lasted four weeks.

Congenital Syphilis or Intertrigo?—Dr. E. L. Cocks presented a baby of two months with redness and scaliness of the lower abdomen, buttocks, inner surfaces of the thighs, and lower extremities, for opinions as to diagnosis.

Dr. Kinch believed it to be specific on account of the marked involvement of the lower limbs.

Dr. Abrahams called it intertriginous eczema and Dr.

Blemian intertrigo. Dr. J. Sobel classines these cases as dermatitis erythematosus eczematoides.

Dr. Oberndorfer considered it an intertrigo with more intense manifestations than usual. Dr. Geyser excluded syphilis. Dr. Leveiss called it a clear case of seborrheal eczema of the newborn modified by moisture. Dr. Gottheil also considered it seborrheal eczema.

Syphilis.—Dr. E. L. Cocks presented a mother and two daughters with syphilis. Seven months ago the mother had chancre, syphilide, iritis, and mucous patches. Despite explicit directions as to its contagious nature and its serious consequences, a daughter of thirteen was attacked four months ago with a chancre of the right tonsil and a subsequent syphilide. Three months ago the second daughter presented herself with a specific throat and a macular syphilide.

Dr. J. Sobel remarked that instances of family syphilis were not uncommon, and very deplorable, to put it mildly.

Dr. L. Weiss suggested that syphilis be placed on the list of reportable diseases and under the same supervision of the local health board as tuberculosis. Dr. Gottheil added that infection by the mouth was not rare, and often explained many obscure and mysterious cases.

Parasitic Eczema.—Dr. R. Abrahams presented a woman who for ten years has had an irregular red, hot, scaly lesion of the lower abdomen and thighs. In addition, for some months, the flexor surfaces of the forearms showed a papular lesion, which, on account of some central depressions, suggested lichen planus. Dr. Kinch thinks it eczema and lichen planus. Dr. Bleiman says that the thighs and genitals show eczema marginatum and the arms lichen. Dr. Oberndorfer considers it an atypical case of psoriasis. Dr. J. Sobel looks upon the condition as eczema, mycotic below, papular above. The excessive scratching has modified the picture and the arms show the retrogressive eczema papules, which, as Gottheil states, so closely resemble those of lichen. Dr. L. Weiss says it is eczema marginatum aggravated by acute attacks. Dr. E. L. Cocks calls it eczema and lichen. Dr. Gottheil states that it is not psoriasis and not lichen, but mycotic eczema.

Herpes Tonsurans Maculosus et Squamosus.—Dr. R. Abrahams presented a girl of thirteen with scaly lesions of various shapes and sizes over the entire body and part of the face. There was a slight amount of itching.

Dr. Kinch would call it seborrheal eczema and advises antiparasiticides. Dr. Bleiman stated that the lesions on the forehead and behind the ears resembled those of seborrheal eczema. Dr. J. Sobel stated that apart from the statements of the previous speaker, the thickness of the scales, their oiliness, the greater elevation of the lesions, and the infiltration of the skin militated against pityriasis rosea. Dr. Oberndorfer, Cocks, Weiss, and Gottheil agree as to the diagnosis of seborrheal eczema.

Vitiligo.—Dr. Blennan presented a woman with lesions of the face, arms, and body.

Eczema Marginatum.—Dr. J. Sobel showed a patient with marginate lesions of the suprapubic region and thighs.

Gumma of the Glans Penis.—Dr. J. P. Oberndorfer presented a patient with a gumma of the glans penis in order to demonstrate the great difficulty at times of differentiating from a large ulcerating chancroid. No history of a previous syphilitic infection was obtained; the patient had not had intercourse for two months, having been confined in a hospital. Dr. L. Weiss advised rapid and heroic treatment. Dr. Gottheil stated that histories in these cases were useless; a diagnosis must be made from what you see.

Chronic Papular Eczema.—Dr. R. Abrahams presented a child who for the past eight weeks has had a papular scaly eruption of almost the entire body. Dr. L. Weiss calls it eczema seborrhœicum psoriatiforme. Dr. Kinch considers it a chronic eczema or lichen. Dr. Cocks calls it dermatitis seborrhœicum. Dr. Oberndorfer says it is lichen planus [illegible], complicated with seborrheal eczema. Dr. Bleiman calls it keratosis follicularis, and Dr. Gottheil believes it to be congenital follicular keratosis.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 3, 1901.

Herman Knapp, M.D., Vice-President, in the Chair.

Wesley M. Carpenter Lecture.—"Pediatrics in America before 1800." Dr. A. Jacobi was the lecturer. He expressed his indebtedness for the historical data to Dr. F. R. Packard and to the librarian of the College of Physicians of Philadelphia, to Dr. Ellsworth Eliot of New York City, and to the Surgeon-General's Library, Washington, D. C. The first case of hereditary syphilis with which he was familiar had been reported by John Winthrop of Boston. A woman after confinement having been troubled with a sore breast, and no one knowing at the time that she was diseased, no less than sixteen persons became infected with syphilis through efforts made to relieve her by sucking and drawing the breast. The earliest treatise on a medical subject published in this country was by the Rev. Thomas Thatcher of Boston in 1677. It was entitled "A Brief Rule to Guide the Common People of New England how to Order Themselves in the Smallpox or Measles." At that time, morbilli and variola were looked upon as similar, if not actually identical. In 1713, measles occurred in many places in New England, and there was a very extensive and malignant epidemic in 1758, which carried off over 1,800 children in Charlestown, S. C. Measles was complicated with angina in some of the cases reported at this time. All the symptoms of measles without the eruption had been observed by Dr. Benjamin Rush in 1773, 1783, and 1789, and many of these same persons had subsequently become sick with ordinary and typical measles. Measles, influenza, and angina were said to be the usual beginning of epidemics; dysentery, yellow fever, and plague developing later. Influenza was a frequent visitor from 1647 to 1780, the epidemic of 1761 being characterized by an inflammatory fever, and that of 1772 by measles and angina. A practice in vogue at that time was inoculation with smallpox as a means of mitigating the severity of the influenza. Dr. Jacobi said that he had already directed attention to an article published by Goldschmidt in December, 1889, in which the statement is made that a very large number of children under twelve years of age, who had been properly vaccinated, had exhibited an unusual immunity to influenza. In 1793, influenza had been exceedingly malignant in New York City, being complicated with angina. In 1735, diphtheria had broken out in Kingston, N. H., and it is noted that of the first forty cases not one recovered. This "distemper" did not reach the Hudson River, we are informed, until nearly two years afterward. The Selectmen of the town of Boston issued a proclamation in 1736 regarding the disease and the opinion of the medical practitioners of that day. The physicians expressed the opinion that the "distemper" was apparently not communicated from person to person, and they thought it proceeded from some affection of the air. The mortality at that time was said to have been very low. The treatment recommended was gargling the throat with a mixture of honey, alum, and the sharpest vinegar. Many of the articles published at this period were written, not by physicians, but by clergymen. In June, 1760, an article appeared on "Angina Malignum or Putrid Sore Throat," a disease which was said to have attacked children, especially since 1746. It was advised that no attempt be made to combat the inflammation by bleeding. This communication was printed anonymously, but has been attributed to Dr. Benjamin Rush.

For lack of time, Dr. Jacobi read only a portion of his address.

Therapeutic Hints.

Mucous Patches.—

℞ Chloral hydrate . . . gr. cl.
Tincture eucalyptus . . . ℥ cc.
Water . . . ʒv.
M Sig. Apply.

—Lutaud.

Bed Sores.—If the nurse is competent, this painful complication will rarely require treatment. It is advisable to rub the parts upon which the patient rests with alcohol, and daily sponging of the entire body with warm water and then with alcohol will add greatly to comfort. Should a suspicious spot of redness present itself, remove the pressure therefrom by an air-cushion, and prevent the folds of linen pressing upon the patient. Dry dressings are preferable to moist ones for bed-sores, and oxide of zinc in powder or ointment is one of the most valuable remedies; acetate of aluminum has also a very beneficial effect. At times, considerable loss of substance is found, giving rise to a very foul odor; in these cases a charcoal poultice acts remarkably well.—*Rotch.*

Chloroform is now very seldom used in the Dublin hospitals. The patient is first put under the influence of nitrous oxide, and when anæsthesia is secured it is prolonged by means of ether.

Dr. Mundé recommends vaginal injections of bromide of potash, 1 dr. to a pint of water, in cases of so-called irritable uterus, diffuse pelvic pains and hysterical neurosis in various parts of the body.

In the Philippines, the insurgents dress wounds with dry salt or strong brine, for lack of the usual antiseptics, and wounds from firearms heal under it in four or five days.

Peanuts have the faculty of absorbing alcohol and preventing it from demoralizing the nerves and upsetting the thinking machine, without entirely curtailing its exhilarating effects. The large proportion of oil in the peanuts accounts for this result. A good wineglass of olive oil has the same effect.

The passage of the catheter in urinary diseases is a surgical operation, and should be considered as such. It is not merely a manœuver, rashly and indiscriminately to be undertaken.

In Biliary Lithiasis, Dr. Stanley M. Ward finds that if the patient will eschew fats and take 1 dr. of phosphate of soda in hot water three times daily for six months, then twice for three months, and continue the dose before breakfast for the balance of the year, recurrence is very rare.

The injection of a glass syringeful of lemon juice into the nose, after it has been cleansed of clots, will stop bleeding after everything else has failed.—*Massachusetts Medical Journal,* September, 1901.

In Incontinence of Urine in children, antipyrine has proved to be useful in large doses. Take 2 dr. of antipyrine and dissolve it in 1 oz. of water and add 1 oz. of alcohol. Take one teaspoonful at bedtime.

Balsam of copaiba is an excellent remedy for chilblains; paint it on once a day or more.

The following is Vidal's formula for seborrhœa sicca of the scalp: Precipitated sulphur, fifteen parts; castor oil, fifty parts; cocoa butter, twelve parts; balsam of Peru, two parts. Thoroughly mix the sulphur and castor oil, add the cocoa butter with the aid of a gentle heat, and finally the balsam. Rub into the scalp.

Agaricin in doses of ¼ to ½ gr. is a valuable remedy in the night-sweats of phthisis.

A thin paste made by mixing iodoform in balsam of Peru is an excellent application to chronic indolent ulcers. Over this, place a dressing of bichloride-of-mercury gauze.

Dr. Sidlo, long ago, claimed to have cured many cases of ozæna by daily washing out the nasal cavities with a 2-per-cent. solution of chloride of potassium, to which 10 per cent. of glycerin has been added. This is followed by inserting rolls of cotton soaked in a mixture of one part of glycerin and three parts of water, the tampons to remain in place for one hour.

Phosphorus in full doses is said to be very beneficial in the treatment of some cases of goiter.

A lotion made of 1 dr. of permanganate of potassium to one pint of water is very effective in counteracting the odor of sweating feet.

Chapman calls attention to a diagnostic sign in myxœdema which has often proved useful. As is well known, puffiness of the eyelids is a sign of Bright's disease. So, too, is it a symptom of myxœdema due to the collection of mucin. So that when the urine is normal and puffiness of the lid is a symptom, the possibility of myxœdema being the cause should be kept in mind.

Dr. Ry reports thirty-two cases of night-terrors in children, in all of which adenoids were present in the naso-pharyngeal vault, and when these were removed, the nightmare ceased. He, therefore, concluded that adenoids are a common underlying cause of this trouble.

Fissure of the Nipple has been very successfully treated by many physicians with orthoform. A few drops of a saturated solution of orthoform in 80-per-cent. alcohol is applied directly to the crack, and a dry compress is then placed above.

The Treatment of Ozæna with antidiphtheritic serum seems to have many prominent advocates. Such specialists as Mgvind, Cathetin, Kyle, and King report good results following this plan.

Haffkine's Serum.—The statistics of the plague in Bombay seem to have established the fact that Haffkine's plague prophylactic is an effective serum for immunizing patients who have been exposed to the disease. Out of 3,814 inoculated persons in the Khoja Mussulman community but three deaths occurred, while among 9,516 uninoculated persons fifty-nine deaths occurred

The Treatment of Pneumonia by serum therapy has not been attended with sufficiently marked results except to give encouragement for its further trial.

Strychnine is the drug most commonly used to sustain the heart, and many advise that it be given in full doses hypodermically because the stomach is often so disturbed as to delay its absorption.—*Journal of Medicine and Science,* August, 1901.

In Acute Gonorrhœal Epididymitis, Setz has great faith in guaiacol. He first washes the parts with soap and ether, and then applies a 10-per-cent. ointment of guaiacol in vaseline.

Many physicians prefer the bromide of strontium to any other form of bromide in the treatment of epilepsy, because it can be continued for months without any of the deleterious effects which attend the use of the potassium salt, and can therefore safely be given in doses large enough to control the fits.

Lime in the Eye.—Wash the eye thoroughly with a large quantity of warm water—for a little water but adds to the trouble by slacking the lime—and then introduce a solution of sugar and water. This is superior to solutions of vinegar or dilute acids, because sugar forms an insoluble compound with lime.

Whatever else you do in internal carbolic-acid poisoning, give at once a large dose of alcohol—whiskey, brandy, rum, or gin will answer—and repeat it often.

Objections to Extirpation of the Gasserian Ganglion.—C. H. Hughes (*Alienist and Neurologist*) summarizes his reasons as follows: (1) The curability of the disease by medication if rightly and vigorously followed up. (2) Trifacial neuralgia is not a disease exclusively of the ganglion. (3) It is not a disease exclusively confined to the fifth nerve. (4) Medical effect equal to that of the operation can be secured by proper means. (5) Because of the irritation, trophic, or paralytic sequences of this formidable operation.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending October 26, 1901:

	Cases.	Deaths.
Measles	130	4
Diphtheria and croup	213	37
Scarlet fever	117	7
Smallpox	8	3
Chickenpox	26	..
Tuberculosis	235	154
Typhoid fever	77	25
Cerebrospinal meningitis	..	

Statistics of Suicides.—The New York *Sun* of October 6 published the following remarks on this subject. "Two peculiarities are shown in the recently published figures of suicides in American cities—the recession of natives of Germany from the head of the list which they long held, and an increase in the number of suicides among colored people. In the last published report on the subject in this city, all boroughs, it was seen for the first time that there were more suicides by natives of the United States than by those of Germany, though the disparity was very small. The change is explained in part by the fact that while the number of German men who commit suicide is larger than that of male suicides of any other country, suicide by German women is comparatively rare, and gets rarer each year. The suicides of colored people have been more conspicuously observed in the large cities of the South than in Northern cities, where the colored population is small and is not increasing, and the explanation of it is found in a single phrase, city life. Colored residents of farms or small towns seldom commit or attempt suicide; it is in the large cities, where the struggle for existence is under conditions most unfavorable to colored men, that a few of them overcome their repugnance to such an act of violence. In proportion to the total population, suicides among Englishmen residing in the United States are very much more frequent than among residents of Irish birth. Among male natives of France and Switzerland in the United States the rate of suicides is high; among women from France or Switzerland there is practically none at all. In respect to the total number of suicides compared with the population, Chicago and San Francisco rank highest among American cities. Baltimore and Richmond are low on the list. In New York City the ratio of suicides is higher in Queens than in the Bronx."

Treatment of Lumbago.—Plique (*Presse Médicale*, Paris, July 20, 1901) says: "In vigorous subjects the abstraction of blood constitutes the best, the most rapid, and the most efficacious treatment. Vapor baths are uncertain. Hot applications diminish the pain, though caution in their use is necessary, lest they cause burns lasting longer than the lumbago. Camphor and chloral hydrate are frequently successful. At the height of the attack, massage can only be used with gentleness and moderation. Slight spraying with methyl chloride over a large area is more successful than intense local action. In obstinate cases, dry faradization, though painful, is very efficacious. The current should be as strong as the patient can bear, and should be continued till the whole back is reddened. Interachnoid injections of a very weak cocaine solution give great relief. Better, because less dangerous, is the epidural injection made through the coccygeal ligament, between the dura mater and the osseous column. Subcutaneous injections of morphine are not to be recommended. Instead, a mixture of antipyrene and cocaine may be injected. For traumatic lumbago, massage and prolonged baths are indicated. In pure rheumatic lumbago, the salicylates have no action. In prolonged cases oil of turpentine in capsules or emulsion seems to have some effect. In other cases it may be necessary to treat anæmia, constipation, etc. In all cases, hygienic measures, to prevent chill and exposure, are useful. It must not be forgotten that lumbago is sometimes due to aneurysm."

Treatment of Inoperable Cancer.—The conclusions arrived at by Alfred Cooper, F.R.C.S., and expressed in *The Lancet*, October 12, with regard to the remedies recommended in the treatment of inoperable cancer are as follows: (1) That in cases of inoperable sarcoma, more especially the spindle-cell variety, the patient should have the option of Coley's fluid given to him, since a certain number of cases have been cured. (2) That in cases of inoperable cancer of the breast, in women of about forty years of age, in whom the menopause has not occurred, the operation of oophorectomy should be proposed, and this treatment may be combined with thyroid feeding; (3) That in cases of inoperable rodent ulcer, and in the superficial malignant ulceration in other parts, the Rontgen rays give a good hope of improvement; (4) That in cases where these other methods are declined, or are inapplicable, the internal administration of celandine is worthy of trial, and when the case appears quite hopeless, morphine should be pushed without hesitation; (5) Finally, Mr. Cooper would suggest that, before trying any of these remedies, the risk should be fully pointed out to the patient that the faint hope, that most of them afford, should not be magnified, and that the discomfort of treatment should be fully discussed; in fact, the surgeon should not do more than offer the treatment, and leave the patient to accept or refuse it.

Human and Bovine Tuberculosis.—Dr. E. R. Brush of Mount Vernon, N. J., says: "One simple fact that strengthens my belief that human bacillary tuberculosis is all derived from the bovine species is that where this animal does not exist, pulmonary consumption is unknown. The Kirghiz on the Steppes of Russia who have no cows have domesticated the horse, using his meat, milk, and skin, and a case of pulmonary tuberculosis has never been known to exist among the tribe. The Esquimau has no cows, neither has he pulmonary consumption; and I think it can be laid down as a fact that where dairy cows are unknown, consumption is unknown. He further says that the reason that tuberculosis is not more frequently transmitted from cattle to man is accounted for in the difference of temperature. A germ cultivated in the cow is a tropical growth, because her average temperature is between 101° and 103°. The human race, by this mode of illustration, represents the temperate zone. The bacillus introduced from the cow into the healthy man finds a difference of temperature of four or five degrees, and although it may live, and in a lessened degree increase, it does not become virulent until, from some other cause, the temperature of the man is increased, when it rapidly multiplies, and thereafter creates its own proper temperature, such as we find in most cases of tuberculosis.—*Sanitarian.*

New Laboratories for Paris.—A special mission was appointed some time ago, says the *Pharmaceutical Journal*, under the presidency of M. Léon Bourgeois, to inquire into the feasibility of furnishing the Conservatoire des Artes et Métiers with the laboratories, which, by virtue of the abundance and variety of work done there, are an absolute necessity. The work of the commission has been concluded, and the report drawn up clearly advocates the building of an addition without delay. The additional surface to be built upon covers 5,000 square metres, so that a handsome edifice in which to do some good and useful work may naturally be expected. These new laboratories will be provided with the most complete and recent appliances to conduct experiments in physics,

mechanics, and chemistry. The probable cost of this proposed addition is estimated at about $100,000, while its maintenance will most likely demand an annual expenditure of $15,000. The prevalent idea is that France has been vastly outstripped by Germany as to applied chemistry, and it is fervently hoped that this action on the part of the government may enable her to turn the tables on, or at least keep pace with, her wide-awake neighbor, for many of the leading industries of Germany owe their origin to French inception

The Origin of European Races.—The London *Globe* says: "It is a sign of the growing importance of anthropology that M. Hamy, a well-known anthropologist, was president of the French Association for the Advancement of Science, which met recently at Ajaccio, Corsica. Hamy took the origins of his particular science in France for the subject of his inaugural address. The immediate founder of the science in France was William Edwards, who was led to publish his observations by the "History of the Gauls" of Amedée Thierry, an erroneous book which seems to have misled Matthew Arnold in his essay on Celtic literature, and all the English critics who follow him. Thierry, on the strength merely of history and tradition, distinguished only two ethnic elements in the French, the Kimry and Galli, whereas there are many elements in this very composite people. Edwards showed that what history called particular races are really mixtures comprising earlier races who have lost their language, customs, etc. The earlier peoples, in fact, amalgamate with newcomers, and give rise to a new subspecies different from the original elements. It is in this way that all the nations of Europe have been built up in the course of ages, not excluding our own, and this accounts for the diversity of types we find in one country as in different countries.

Legislation on Intemperance.—The New York *Tribune*, October 13, says: "The public is now alive to the fact that it must consider dipsomaniacs, or habitual drunkards, as invalids, very much of the same type as epileptics, that their care has become a necessity, and when the drink habit has become uncontrollable, and the poor victim can no longer restrain himself, and becomes crazed with a maddening thirst for liquor, he should be protected and surrounded by every possible safeguard. During the last session of the Legislature of the State of New York, at Albany, there was considerable discussion as to the best method to be adopted for the care, and, if possible, the permanent cure of victims of alcoholism, and also of those addicted to the use of narcotics and other deleterious drugs, as artificial stimulants so destructive to the nervous system. A bill was presented directing the establishment of an asylum or sanatorium where these patients could be committed, either voluntarily, upon the application or complaint of a member of the family of the afflicted sufferer from drink or noxious drugs, or by especially authorized officers of the law. This commitment to be for a term of not less than five years."

Phagocytosis of the Typhoid and the Colon Bacillus.—Giovanni Battiata de Rosa-Cotronei concludes that phagocytosis affects the colon bacillus more rapidly and more markedly than it does the typhoid bacillus. The latter is, therefore, the more virulent. In animals, which have been rendered immune, the phagocytic power is high in regard to both bacilli. An animal vaccinated with one of these germs acquires a high degree of phagocytic power against the other germ. The action is more intense in animals vaccinated with typhoid bacillus, and injected with the colon bacillus, than in the opposite case. Traumatism, anæsthetics, narcotics, pregnancy, and cold are factors capable of retarding, and even of preventing, the phagocytosis of the typhoid and the colon bacillus.—*Lo Sperimentale.*

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended October 26, 1901:

			Cases	Deaths

SOME OBSERVATIONS ON THE SYMPTOMATOLOGY AND DIFFERENTIAL DIAGNOSIS OF APOPLEXY; WITH THE REPORTS OF SEVERAL ILLUSTRATIVE CASES.*

BY THEODORE DILLER, M.D.
PITTSBURG
NEUROLOGIST TO THE ALLEGHENY GENERAL HOSPITAL

THE term apoplexy will be used to include encephalic hemorrhage, thrombosis, and embolism, as a synonym for what is popularly known as a "stroke." No attempt will be made to describe the typical attack of apoplexy, nor those occurring in childhood. It is my purpose rather to speak of the apoplexies in the adult, occurring in unusual situations, and to discuss certain points in the matter of symptomatology and differential diagnosis which I believe to be of importance. It is not my purpose to weary you with the recitation of the details of a large number of cases, but to introduce in the briefest manner possible the main features of a few cases only to illustrate the points I wish to make.

In the first place, the conviction is being more and more forced upon me that the occurrence of apoplexy, without the production of either paralysis or loss of consciousness, is far more common than a reading of the standard textbooks would lead one to believe; and the recognition of such apoplexies must be regarded as of the greatest importance, since they often leave little damage behind, and afford a most favorable opportunity for the institution of such dietetic and hygienic measures as may prevent or postpone a second attack. Again, but one of these two symptoms may be present. I recall several cases of what I believed to be cerebral hemorrhage which came into the Allegheny General Hospital, in which there were sudden attacks of coma without paralysis, and in one of these cases the diagnosis was verified by an autopsy.

Apoplexy Without Paralysis or Loss of Consciousness.—As an illustration of this proposition I desire briefly to mention a case already referred to by me last winter in a verbal report before the academy. The case is that of a priest, aged forty-seven, of an artistic and highly nervous temperament, an artist of no mean ability.

On December 7 last, while watching the children at play, he suddenly became slightly clouded in his consciousness. He stayed himself to keep from falling, and, recovering himself quickly, noticed that he was blind to the right. He retired to the house unaided, and no one knew that he was ill—that he had received a stroke of apoplexy. For two weeks he refrained from work, but did not go to bed.

Examination by Dr. W. K. Walker discovered the left halves of both retinæ to be blind, as shown in the accompanying chart (see Fig. 1). At the time of my examination the patient was nervous and excitable, with a pulse of 125. The heart sounds were normal. Wernicke's hemiopic inaction sign could not be elicited, thus indicating an involvement of the cortical optic centers on the left side or the tracts between them and the primary optic centers on the same side.

Here we have, I believe, a clear case of apoplexy with partial and momentary loss of consciousness, leaving behind it only one symptom by which we can form the reasonable belief that an apoplexy has occurred. Had homonymous hemianopsia not been produced, it is altogether unlikely that apoplexy would have been diagnosed. It is difficult to consider a case like this without having the suspicion enter the mind that many attacks of apoplexy occur which are unrecognized because of the temporary or insufficient symptom, which they produce. In another case of apoplexy occurring in a mother during childbirth with hemiplegia and loss of consciousness, homonymous hemianopsia was produced and is a persistent symptom (see Fig. 2).

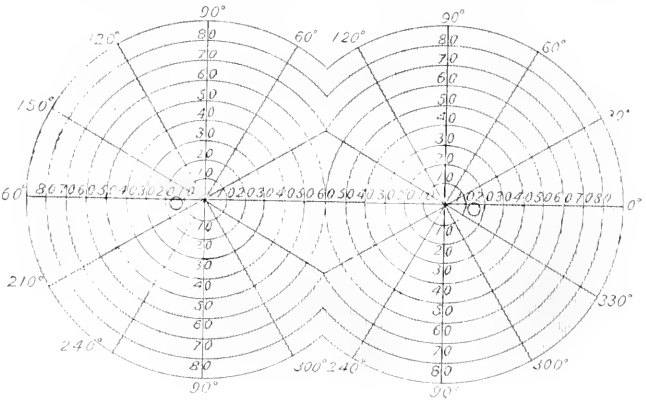

FIG. 1.

While this paper was in course of preparation, it was my good fortune to see within two or three days of each other two apoplexies of the central vessels of the retina. One was probably due to a thrombosis of the vein, the other to an embolism in the artery. In both cases the onset was sudden, but consciousness was not disturbed. The eye-grounds in the two cases presented striking contrasts. Dr. G. E. Curry, to whom I am indebted for the permission to examine these cases, will furnish a description of them.

Apoplexy of the central vessels of the retina, as is well known, is sometimes the forerunner of an apoplexy of a cerebral vessel; and the warning it gives is not to be disregarded.

*A paper read before the Pittsburg Academy of Medicine, September 30, 1901.

Apoplexy Manifesting Itself by Hemiplegia Unattended by Loss of Consciousness.—That an apoplexy may manifest itself by a hemiplegia alone without a loss of consciousness is illustrated by the following case:

A man, aged fifty-eight years, a contractor, while quietly smoking on January 24, 1895, noted his face was drawn to the left; and he was unable to close the right eye. He was fully conscious. When I saw him two years later, the right facial palsy was marked and there was slight but distinct spastic paralysis of the right arm and leg. The right knee-jerk was exaggerated.

At first glance, with the patient's history, the case seemed one of ordinary seventh-nerve palsy, but the electrical reactions of the right face muscles and the right-sided spasticity, with exaggerated right knee-jerk, made the diagnosis of apoplexy clear.

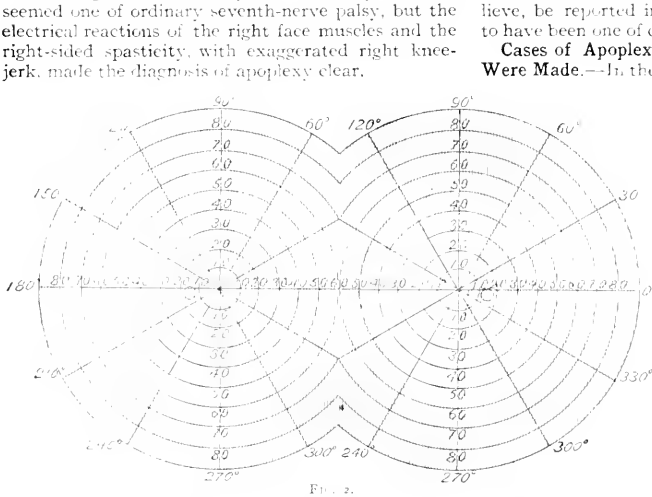

FIG. 2.

Two months after my first examination, the patient awoke one morning dizzy and confused, so that he was unable to stand alone. Within the space of two weeks he regained his usual mental faculties. The hemiplegia was not deepened. In this attack the conditions were reversed, *i. e.* it was attended with disturbance of consciousness without those of motion.*

Apoplexy Producing Loss of Consciousness and Prolonged Mental Disturbance, But Not Paralysis.—The case which, in all probability, was one of thrombosis with secondary softening, was characterized by early and prolonged disturbance of consciousness unattended by paralysis.

The case is that of a very plethoric man, aged fifty-four, an architect by occupation, and a constant drinker.

About two years ago he was struck on the head in a melee, and rendered unconscious, and at the hospital was found to have a right hemiplegia. He recovered entirely from this attack, and was again able to attend to his usual business.

One week ago, after an unusually hearty breakfast, he complained of violent headache. He staggered as though intoxicated, and soon became confused and helpless. At noon he recovered consciousness partially. He soon relapsed into coma again, and so continued for three days. He revived somewhat, but soon relapsed again.

When I saw him he was stuporous, but not comatose. His temperature was 103 and his pulse 90. There was no paralysis; the knee-jerks were unaltered. He was taken to the Allegheny General Hospital, where he remained in a condition of greater or less stupor and mental confusion for three months, and with a temperature, during several weeks, ranging from 102 to 103. He made a partial recovery, and was discharged at the end of three months. I saw him a year later, when he seemed to be in excellent health, except for a minor tinge of dementia.

The several headaches ushering in this second attack, the onset and variability of the coma, the long period of mental confusion, the absence of palsy, and the final approximate recovery were to me all points of interest in this case which could, with profit, I believe, be reported in detail. The first attack seems to have been one of conventional apoplexy.

Cases of Apoplexy in Which Incorrect Diagnoses Were Made.—In the next three cases erroneous diagnoses were made. The first of these is one of thrombosis with secondary softening, in which the diagnosis of brain tumor was made, and it well illustrates some of the difficulties which may be encountered in making a differential diagnosis between these two affections.

A single woman aged sixty, of most exemplary habits, had for ten or fifteen years preceding my examination, been subject to more or less pain in the epigastric region. Gastric cancer and floating kidney had been diagnosed. For two years she had steadily lost in flesh. For three and a half weeks past she had complained of constant headache which was often severe. For two and a half weeks past she had been subject to much nausea and vertigo, and on several occasions had vomited. A week before death some thickness of speech developed. Three days before death stupor appeared and rapidly deepened into coma. The eye grounds were not examined. Paralysis was not a symptom.

The autopsy discovered great degeneration of all the arteries at the base of the brain, the vertebrals being especially stiff and hard, and one of them contained a well-organized thrombus. A spot of softening, the size of a marble, was discovered on the posterior edge of the left cerebellum. Two smaller areas of softening, one in the tegmental region of the left crus and the other in the left optic thalamus, were found.

The symptoms noted in this case, common to thrombosis with secondary softening and brain tumor, are: Severe headache, nausea, vertigo, vomiting, and stupor. The fact that the headaches had existed only three and a half weeks, and that there was general arterial degeneration, were two points which, however, favored the diagnosis of the true condition—cerebral softening. There was some reason for suspecting that the headaches have lasted longer than stated.

In another case of cerebral softening already published,* the diagnosis of hysteria was made by me and two other physicians. The main points in this case are briefly as follows:

A woman, aged fifty-six, became much concerned because of a hand injury which her granddaughter had sustained, and a few days later began to complain herself of numbness in the right hand, and persisted for some days in repeatedly saying her condi-

*Since this was written, I saw a woman who, several weeks ago, was suddenly stricken down with a left hemiplegia with no loss of consciousness whatever. The hemiplegia persists and contractures are now present. Her mind remains unclouded.

*MEDICAL RECORD, April 28, 1894.

tion was growing worse, and then that her leg on the same side was similarly affected. Finally, hemiplegia developed on the paræsthetic side. More than a month was required for the development of these symptoms, and the case was regarded as one of hysteria. But a little later the hemiplegia became more pronounced; stupor, and then coma, with elevation of temperature, developed. The patient finally died, the temperature during a few days preceding death having mounted rapidly up to 106.

An autopsy discovered badly degenerated arteries at the base of the brain, a great narrowing of the internal carotids, each of which contained a firm thrombus. Extensive softening was noted in the left cerebral hemisphere. It need hardly be added that, with the deepening of the stupor into coma and the appearance of temperature, the diagnosis of hysteria was abandoned.

The next case* was one of hemorrhage into the frontal lobe attended with violent and prolonged convulsive movements in which the diagnosis of hysteria was made. The chief features in the case are as follows:

A woman, aged forty-six, while out for a walk, suddenly sank to the ground and at the same time vigorously called for assistance. "There was also a spasmodic, hacking cough, with some spitting of blood." She soon sank into coma and at the same time exhibited violent general convulsive movements, which were maintained for more than half an hour. But no paralysis was apparent. The patient improved. After two or three weeks, when her mind was pretty clear, she was seized with an attack characterized by sudden unconsciousness, right hemiplegia, vomiting, and loss of control of the sphincters. Death occurred a few days later.

At the autopsy a large blood-filled cavity was discovered in the left frontal lobe, which itself was much softened. A layer of blood measuring two and a half by three inches was also found beneath the dura over the left parietal region. A similar but smaller area of blood was found over the right parietal region.

The interesting features in this case are the onset of the first attack, with coma and violent and prolonged general convulsive movements, which led those who first saw the patient to regard the attack as hysterical, and the post-mortem findings.

Sudden Loss of Consciousness with Hemiplegia Due to Causes Other than Apoplexy or Without Apparent Cause.—On three occasions I have witnessed autopsies where the clinical diagnosis had been cerebral hemorrhage based upon a sudden loss of consciousness with hemiplegia. In one of these cases nothing was revealed which could explain the symptoms. In the two other cases rather marked cerebral œdema was present. I believe that the possibility of a general cerebral œdema producing hemiplegia with unconsciousness must be allowed.

As is well known, both abscess and tumor may, even when of a large size, remain latent in the brain for many months, or even years, producing few or no symptoms. These lesions may first declare themselves by producing more or less sudden loss of consciousness with hemiplegia.

I recall a case of sudden unconsciousness, with hemiplegia, to which I was hastily summoned a number of years ago. I learned that the patient had complained in a more or less indefinite way of headaches and general ill-health, and had taken "womb treatment," believing that the symptoms arose from that organ. I discovered, upon dissecting the brain, a large abscess in one cerebral lobe.

Apoplexies Occurring in Connection with Brain Tumors and Brain Abscesses.—As is well known, hemorrhage may occur in or about a brain tumor or abscess and produce symptoms masking those of tumor or abscess, so that the physician without a history may be misled as to the true condition; and, indeed, with the history the indications may not be sufficiently clear. In all cases of brain tumor or brain abscess, the possibility of a complicating apoplexy should enter the physician's mind.

Apoplexy as a Symptom of Paralytic Dementia.—The next case is one in which the question arose (and still remains unsettled) as to whether an apoplectic attack was one such pure and simple, or as to whether it was symptomatic merely in the course of beginning paralytic dementia, which disease, as is well known, is often characterized by such attacks.

A man, aged sixty-two, who had been a *steady* whiskey drinker since the age of twenty-one, was, on the morning of April 6, last seized with an attack which was described as follows: On awakening he talked in a confused manner, like one drunk, and his speech was thick. He had much difficulty in eating his breakfast, used a spoon for a knife, etc. He exhibited no paralysis of any sort, but the mental confusion continued up to the time of my visit, two weeks later.

Examination showed his pupillary reactions, speech, station, gait, and knee-jerks to be normal. Mentally, he exhibited distinct dementia. Asked on three different occasions his age, he gave three different answers. He could not add numbers of two units together, or subtract numbers of a single unit. He misplaced and mispronounced words. His handwriting was more cramped and less legible than before the attack. He normally wrote a clear, bold hand.

This patient was said to have been in excellent health before the attack described, and to have exhibited no mental deterioration whatever. Nevertheless, his mental condition since the attack and the character of the attack itself make me suspect the existence of paralytic dementia, notwithstanding that the age of onset (sixty-two years), the physical examination, and the history argue against this view.

In another case, that of a young man in the early thirties, whom I saw last winter, the history of syphilis, diplopia, convulsive and recurrent hemiplegic attacks, led to the diagnosis of syphilitic thrombosis when the patient was seen in an apoplectic attack. Indeed, this diagnosis was only revised at the autopsy, when the indubitable changes of paralytic dementia were discovered. This case will be reported in full by Dr. W. K. Walker, R. G. Burns, and myself in an early number of the *American Journal of Medical Sciences*.

Yet, the diagnosis of apoplexy was correct enough, so far as it went. But it did not go far enough, *i. e.* far enough to recognize the apoplexy as a symptom of the paralytic dementia.

Apoplexies in Unusual Situations in the Encephalon.—Apoplexies in the pons are probably quite rare. Of these I have two cases to record, the first of which was studied with Dr. J. Hartley Anderson, who, some years ago, made a verbal report of it before this academy.

A gentleman, a member of our profession, aged about fifty-five, had for nearly a year suffered from diplopia. He awoke one morning to find his speech thick, and utterance and deglutition difficult. These bulbar symptoms increased. Slight paralysis of one side and then of the other side of the body appeared.

*This case has already been reported by Dr. Samuel Ayres. See *Pennsylvania Medical Journal*, November, 1897.

The pupils were unequal. Mental confusion, slow, irregular respirations, stupor, and coma followed. Death ensued in a few days.

At the autopsy, Dr. Anderson discovered a thrombus of the basilar artery and bilateral softening of the pons.

In a previous paper* I have reported the next case, one of apoplexy of the pons, and called attention to the great similarity between the symptoms thus produced and those caused by opium poisoning. The symptoms common to both are: Stupor or coma, myosis and slow respirations. It is needless to point out the possible medico-legal significance this fact might have in a given case; for without a history a differential diagnosis would probably be impossible.

In the case I reported, that of a woman, aged sixty-six years, there was increasing stupor over four or five days (when death occurred), temperature ranging from 100 to 103, an internal squint, and twitching of the facial muscles. The respirations were slow (seven to eight per minute) and came in groups of threes. The points which distinguished the case from opium poisoning were: The temperature, facial twitching, the irregularity of the respirations, the ocular palsy, the incompleteness of the coma, and the history of the case (ability to eliminate opium poisoning). I have not yet ceased to regret that an autopsy was refused in this case.

Apoplexies in the cerebellum are not so rare as those in the pons, but occur much less frequently than those of the cerebrum. I desire to report the following two cases of apoplexies in this region:

A man, aged forty-seven, fell to the floor unconscious in attempting to get out of bed one morning. For three days following this attack, he had frequent and violent vomiting spells. He remained in bed five weeks, during all of which time he was subject to attacks of vertigo brought on especially by movement. Severe onsets were attended by nausea and vomiting. Hemiplegia had not been a symptom. When I saw him—three months after the initial attack—vertigo was still a most troublesome symptom. The patient guarded carefully against sudden movements which experience had taught brought on vertigo and vomiting. His gait was slow and uncertain. Sensation and motion were unimpaired, and the knee-jerks were normal. He had had no ringing in the ears. There was no impairment of hearing.

The second case is that of a man, aged fifty-nine years, who, in February, 1900, was suddenly seized with a left hemiplegia. A week later he had fully recovered the lost power in the leg, but only partially that in the arm, which has continued to be partially paralyzed.

On November 26, following, while riding in a street car, his consciousness became clouded, but not lost, and "things swam before his eyes." In getting out of the car, he found himself very unsteady on his feet. He got into a carriage, and after driving a mile was seized with nausea and vomiting, and felt "weak and numb all over." Following this attack, he was extremely dizzy for the next three weeks, and this symptom, in less degree, has persisted up to the present time. He never feels dizzy when sitting or lying quietly. But muscular movement, even slow, careful attempts at walking, bring it on. He has come to avoid all sudden, sharp turns for fear of bringing on this most distressing symptom. He walks in a slow, lumbering fashion, with his feet wide apart, concentrating his attention on the act. Knee-jerks are present, and both are below normal in excursion. There is no deafness or tinnitus.

Following the second attack no increase of the left hemiplegia occurred.

Medical News, May 29, 1897

Two noteworthy features of both of these cases are the appearance of vomiting and vertigo as early symptoms, and the stubborn persistence of the vertigo as the chief after-symptom.

In conclusion, it is perhaps only trite to say that apoplexy is only a symptom—not a disease in itself. Hemorrhage or thrombosis can only occur when the blood vessels are diseased; and embolism can only occur by the entrance of a foreign body in the blood stream. The rise of blood pressure is the most frequent determining cause of apoplexy, and in this single proposition we have our most significant hint for prophylactic treatment.

Westinghouse Building.

SOME REMARKS ON THE ETIOLOGY OF APOPLEXIES.*

By W. K. Walker, M.D.,
Dixmont, Pa.

In Dr. Diller's interesting series of cases this feature stands out prominently; the varying clinical features presented, however accurately they may enable us to determine the character and to locate the lesion within the complicated structure of the brain, are due to destructive changes in brain tissue which we can but little modify by treatment; and this because each case represents the termination or final culmination of conditions and causes which have probably been operative for years. Without consideration of this etiologic aspect, therefore, it seems to me that the lesson to be taken from the paper to which we have listened would be lost.

Whether of cerebrum, cerebellum, or pons, the primary lesion and principal underlying cause is pathologic change in blood-vessel walls. So gradual may this have been in its development, insidiously advancing without the production of symptoms (indeed, the subject is commonly the picture of health and vigor), that the final result in sudden damage to neural tissue often occurs without warning.

That "a man is as old as his arteries" has long been an axiom. Osler says that longevity is thus made a vascular question, and, also, that to the majority of men death comes primarily or secondarily by this portal. Bad quality of the arterial tubing may be inherited, but "a vessel which at the outset was well developed may be modified by the far-reaching influence of post-natal diseases and the influence of various poisons" (Berkley). With disturbance of cell-nutrition consequent upon damage to vessel-walls, we have the production of symptoms varying with the anatomic character and concomitant function of organs involved. With increasing knowledge of the causes and pathology of these changes, the relation of vascular degeneration to nerve lesions assumes increasing importance, many diseases of the nervous system formerly described as trophic, vasomotor, etc., now being determined to be of vascular origin. Results of recent investigations in neuropathology show that the chromatic substance, the most important constituent of nerve cells, is more susceptible to the effects of disordered circulation than to the action of most bacterial toxins (Ewing), and we know that in those forms of insanity which are to-day based upon a precise morbid anatomy—*e.g.* syphilitic insanity, paralytic dementia, senile dementia—the essential lesions are of the vascular apparatus. Although vascular in origin, the clinical manifestations are due to resulting interference with nutrition or destruction of various groups of neurons, with consequent impairment or abolition of their functions.

*Read in the discussion of Dr. Diller's paper on apoplexy before the Pittsburg Academy of Medicine, September 30, 1901.

That the manifestations should vary so greatly when the higher cerebral centers suffer as a result of these changes can be explained only on the grounds of variations in vulnerability of different portions of the brain, and in nervous instability, either inherited or acquired by modes of living. Given, then, an inherited vulnerability of the arterial tubing, a relatively slight influence of the factor of irritant poison may be required to produce serious damage in blood-vessel walls.

In addition to the factors named, there is frequently operating the inciting one of high functional activity, which, in a given individual, determines the location of the lesion in a certain set or group of neurons. "The life of a blood vessel in the main depends upon the use made of it;" enfeeblement by stress would, therefore, predispose particular vessels, or sets of vessels, to injury when subjected to the special force of poisons introduced into the blood stream. One of Dr. Diller's cases well illustrates how overwork of a complex center may determine location of the lesion. I refer to the case of hemianopsia which I saw about six weeks after its development. The patient, a Roman Catholic priest, is also an artist of recognized ability and prolific brush; the exercise of his talents in this line has been his one "recreation" in a life of unusually arduous labors associated with anxiety or stress. Excessive functional activity of the representative visual centers was, doubtless, the potent factor determining the location of lesion in the walls of blood vessels supplying the overworked area. Of interest in this case was family history, which revealed blood-vessel vulnerability on the father's side, with marked nerve instability on the mother's, with personal history showing both tendencies existing in the patient in an exaggerated degree.

Another instance within the domain of organic degenerative processes is furnished by the lesions of paralytic dementia, a disease in which the minute vessels of the cerebral cortex become profoundly involved, degeneration of cortical cells resulting, or at least progressing, with the vascular degenerative process. It was early noted that this disease most frequently attacked those subjected to mental overwork, *i. e.* to excessive functional activity of the higher cerebral centers, and to-day it is generally conceded that stress, either relative or absolute, is important as one of the factors in its production. Though said to be "more gradual in its commencement than any other known disease," paralytic dementia is, in reality, not more so than is disease of like pathogenesis in other organs, viz., kidneys, liver, and heart; in all there may be advanced degenerative vascular lesions associated with gradually progressive parenchymal damage, usually far advanced when first made manifest by symptoms.

As determining which cells or groups of cells are the first to give way, the "selective" action of the various poisons (notably that of syphilis) has been described; this so frequently gives the impress to a clinical picture that the cause of the disease, it has been said, is revealed by the character of the symptoms. We more and more realize, however, that a high degree of functional activity is a most important factor in locating the lesion. As an instance of the selective action of the syphilitic virus, involvement of the centers of vision and the muscular mechanism of the eye is one commonly used. The complex mechanism of binocular vision, so delicately adjusted and so constantly subjected to stress and strain (whether by refractive error or actual overwork), is precisely the one which best illustrates the operation of the principle I have referred to.

As initial causes of vascular degenerative diseases, syphilis and alcohol will probably always be the most frequent and most potent because of their widespread influence, their virulence, and the fact that their action is continuously exerted over a long period of time. Other toxins, however, are known to exert their baneful influence upon blood-vessel walls and to be productive of degenerative conditions heretofore considered characteristic of a few special poisons. With paralytic dementia again illustrating the etiologic importance of these, the recently expressed conviction of Regis is significant. Previously giving the chief occasional cause of this disease as syphilis, he now believes that tuberculosis or any other infection may be the etiologic factor in the production of paralytic dementia, and not necessarily always syphilis.

Indicative of the increasingly great importance which is given to autotoxic substances as causes of disease is the theory advanced by Dr. Ford Robertson in the *British Medical Journal* of June 29, 1901, which makes paralytic dementia (and this disease best illustrates the insidious progress of vascular degenerative lesion) a disease due to a toxæmia of gastrointestinal origin; toxins developed by the excessive growth of bacteria which normally inhabit the alimentary tract, particularly affecting the nutrition of the vessels of the central nervous system, and more especially those of very vascular regions, such as the cerebral cortex. He believes that the toxæmia exists for months or even years before the first manifestation of nervous disorder. Whether later developments will bear out this theory of the disease remains to be demonstrated. At all events, we know that cerebral apoplexies are frequently met with in pale, nervous individuals of the type characterized by indigestion, who present no history of indulgence in alcohol, nor evidence of syphilitic infection. In the light of recent discoveries in the field of neuropathology, which are in concordance with the views here quoted, we must incline to the belief that toxæmias of gastrointestinal origin may be potent factors in the production of vascular degenerative disease, which, in turn, is the cause of many degenerative neuroses.

The importance of the most virulent poisons of syphilis and alcohol as causes of the well-marked cases of degenerative vascular and nervous disease instanced in Dr. Diller's cases is quite generally recognized. The influence of these same factors is not so generally admitted, however, in early involvement of an organ which must express its condition in terms other than those of pain, disordered or changed secretions, etc.; I refer to the higher brain centers, which suffer in precisely the same manner as other organs, but whose altered or perverted functions are made manifest by such symptoms as lowered capacity for work, forgetfulness, sleeplessness, changes of humor, irritability, suspicions, changes in the natural affections or in habits of education, morbid emotions, obsessions, confusion, etc. Symptoms of this order are frequently encountered in active individuals in the prime of life and later, or in those of earlier years who have been subjected to the influence of bacterial, autogenous, or other poisons, and they become here of equal significance with perverted secretions of glandular organs, or failing cardiac power, when kidneys, liver, or heart suffer disease of like pathogenesis. In short most of the symptoms named, though oftenest considered in connection with the functional psychoses, may also be the precursors of grave organic degenerative disease of the nervous system. In the first class the cases are produced by exhaustion or perverted nutrition of groups or systems of neurons, while in the second class they are due to interference with cell nutrition, progressing to more or less com-

plete destruction, because of extensive changes in blood-vessel walls. With the greater light which chemistry and neurohistology are shedding upon the complex nutritive processes going on within the nerve cell, the causative factors of vascular degenerative disease must more and more occupy our attention.

Appreciation of the far-reaching and destructive influences of the various poisons upon blood-vessel walls, as well as upon nerve cells, brings practical results. The known tendency of all—whether resulting from infectious disease suffered in early life, from altered and perverted processes in body chemistry, or from the virulent poisons of syphilis and alcohol, to expend their forces upon the vascular walls with consequent deterioration or destruction of the functional units of organs, whether glandular, muscular, or of the delicate and complex structure of the brain and nervous system—should lead to prompt, energetic, and prolonged treatment of one known to have been subjected to their influence; and when family history reveals inherited instability or vulnerability of nervous tissue, early appreciation of the significance of the vague symptoms of disturbed circulation within the brain will enable us to do much to prevent the more serious developments and complications which we are so powerless to cure.

It would seem that in no other class of diseases is the influence of heredity so readily traced as in those due to vascular degenerations, nor more plainly manifested the truth that not the disease itself is inherited, but rather "a peculiar type of tissue, which renders the individual peculiarly susceptible to the influence of morbific agents."

CONCERNING THE CLINICAL SIGNIFICANCE OF THE KLEBS-LOEFFLER BACILLUS.*

By ADOLPH RUPP, M D
NEW YORK.

In his own words, Professor Osler narrates the following significant anecdote, full of wisdom and food for reflection, "of that true Asclepiad Ludwig Traube, who, adding probity to learning, sagacity, and humanity, reached the full stature of the Hippocratean physician. When acknowledging some error, he would say—often in a soft, meditative manner, as if quietly reproaching himself—have we observed all the facts of the case? Yes. Did the art permit of a judgment on the facts under consideration? Yes. Did we reason correctly on the data before us? No. *Wir haben nicht richtig gedacht.*" No, our thinking was incorrect. This anecdote embodies much that is significant and encouraging for all practitioners; and the sterling sentiments it illustrates are an apology and a justification for any practitioner who elects to take an active part in the discussions that have for their object a satisfactory solution of the problems that have been introduced into practical medicine by bacteriological experimentalists. The encouraging part of the anecdote is the surpassing importance allowed to *thinking*. Facts alone, however carefully sifted, do not constitute science. They become an essential part of science after thinking processes have made their significance and meaning apparent, and their relations and inter-relations evident. Thinking processes are experimental in all minds; and human minds are quite true to themselves when influenced by what Fränkel, without much ingenuity, is pleased to call a dangerous Dreibund, or triple alliance of obstinacy or perversity, stupidity, and prejudice. But Fränkel and von Behring—the latter quotes the former approvingly—are not dominated in their judgments by unprejudiced and true psychological principles when they console themselves with an easy and self-satisfied assurance that this Dreibund, or triple alliance of perversity, stupidity, and prejudice exerts its baneful influence only on those who do not share their views. In so far as the value of the methods employed for developing laboratory facts is concerned, the practitioner, as a rule, is no competent judge, be he an "enthusiastic believer" or merely "a sincere skeptic." But taking the facts, ready made as they are presented to him by scientists, and applying them to the exigencies occurring within his own practical domain, the practitioner has a human right to place some confidence in his own judgment concerning the practical operation of such facts. And if this right be denied him, he is debarred from giving evidence as to his sagacity and scholarship, and his professed probity will be nothing better than veiled hypocrisy.

It is from this point of view of the student practitioner that the following brief study concerning the clinical significance of the Klebs-Loeffler bacillus has been undertaken, and is presented here this evening. From our study it will be seen that the surest fact concerning the clinical significance of the Klebs-Loeffler bacillus is that it is still in an evolutionary stage.

The knowledge we have of it is far from complete, and is the result of much patient observation and thought, not of any one observer, but of many. Nor has its present significance been worked out in the dead-house and laboratory only; but hospital clinicians and private practitioners have contributed important facts, reflections, and criticisms. The observations begun by Klebs, improved upon by Loeffler, and completed by Roux and Yersin, and von Behring chiefly, seem to encourage those who assume to speak for the scientific or laboratory side in claiming that "the problems concerning diphtheria have been completely solved so far as its practical aspects are concerned" (Biggs). But when we take a survey of diphtheria from the clinico-historical point of view, we find it difficult and impossible to conclude otherwise than that "diphtheria remains perhaps the most obscure and complex of all the infective diseases in *its causes* and favoring conditions" (Creighton).

This lack of harmony existing between the laboratory view and the clinico-historical view is not due to the machinations of Fränkel's triple alliance, but rather to differences of definition and clinical interpretations avowed and acted upon respectively by both parties. Besides, many observant practitioners are apt by habit and inclination to look less favorably upon experimental harmony and consequence, which they by no means deny and neglect, than they are eager to welcome a happy empirical and long-hoped-for realization concerning which there can be no two opinions; not that they love science less, but the realization of an experimental promise more.

During the past ten years or so, the practitioner has been having drilled into him that there are practically at least three kinds of diphtherias: (1) Laboratory or experimental diphtheria, that is, the specific Klebs-Loeffler bacillary toxin diphtheria; (2) clinical diphtherias, in which Klebs-Loeffler bacilli are assumed to be the predominating, if not the only, etiological factor, and (3) clinical diphtherias, in which Klebs-Loeffler bacilli are absent, or, for various reasons, are not detected.

All that the practitioner, as a rule, knows of laboratory diphtheria, he knows through laboratory reports; and, as a matter of knowledge and faith, it is purely theoretical.

Concerning the status of the Klebs-Loeffler bacillus in many cases of clinical diphtherias, the practitioner here also takes much on trust. But in

*Read at the May meeting of the City (Charity) Hospital Alumni Society, 1901.

these cases his faith is directed and controlled by his own daily experiences and inferences, besides by hospital clinicians and fellow practitioners. The facts and inferences concerning the Klebs-Loeffler bacillus, reported by various observers, are always interesting; but the reporters individually are not always consequential in their inferences, and, taken collectively, there is a lack of harmony as to what has been seen and inferred by them. In the *American Journal of the Medical Sciences* for April and May, 1889, five years after Loeffler had made his classical report on the bacillus that bears his name, Professor T. M. Prudden published a bacteriological report of twenty-four (24) fatal cases of clinical diphtherias, and "the bacillus of Loeffler," he says "was not found in any of them." These cases had all been examined with especial and particular scientific care and precision, and the nice work that had been devoted to their examination was at the time highly praised by those who claim to know just exactly what is what in such matters. But hardly more than one year after the publication of Professor Prudden's report, an experienced clinician commented thereon in the following interesting way: "These cases for a time misled Dr. Prudden and the entire medical profession in this country, for the absence of the Klebs-Loeffler bacillus in twenty-four cases of clinical diphtheria could not be the cause of diphtheria." "And," continues J. Lewis Smith, "if I am correctly informed, Dr. Prudden now (a year later, 1890) believes that the disease in all these fatal cases was pseudo-diphtheria." All this simply proves what? Nothing more than this: An expert microscopist, pathologist, and bacteriologist failed to find the Klebs-Loeffler bacillus in twenty-four undoubted cases of true clinical diphtherias that had all ended fatally in various typical ways. Several years later, at Paris, Martin examined two hundred cases of clinical diphtherias and found the Klebs-Loeffler bacillus *absent* in sixty-three of them. And at about the same time, Heubner, at Leipzig, found this bacillus absent in thirty-six out of one hundred and thirteen cases of clinical diphtherias. Thus, in about one-third of the cases of clinical diphtherias examined by these two competent observers, the Klebs-Loeffler bacillus could not be found. But as time goes on, other observers claim a greater success in detecting this bacillus in cases of clinical diphtherias. Bazinsky, in his memoir on diphtheria (Nothnagel's Handbuch) tells us that he and his assistants are so very careful in searching for Klebs-Loeffler bacilli that only in about 3 per cent. of their cases of clinical diphtherias does this bacillus escape detection. And von Behring, citing Kossel, says that after an extraordinarily careful analysis of two hundred and sixty-five cases of clinical diphtherias it was found that only 8 per cent. of them lacked the Klebs-Loeffler bacillus, and that, besides, no deaths of diphtheria in sequelæ occurred in the cases that had no Klebs-Loeffler bacilli.* But, on the other hand, Fred. Grant Burrows, A.M., M.D., after a painstaking analysis of over 2,000 cases of clinical diphtherias treated by him in the Boston City Hospital, during 1899 and 1900, found the Klebs-Loeffler bacillus absent in over 200. And contrary to Kossel's experience 26 per cent. were fatal.† Besides this great irregularity as to the presence or absence of the Klebs-Loeffler bacilli in cases of clinical diphtherias examined and reported by various observers and investigators, there are other facts to be taken into account.

*Bibliothek v. Coler, "Diphtherie," page 104.

†"A Clinical Study of Diphtheria," etc.—*American Journal of Medical Sciences*, January, 1901.

1. The presence of the Klebs-Loeffler bacilli in any case of diphtheria is no mark indicative of its severity or otherwise.

2. Park (Bacteriology) tells us that the most virulent specimen of Klebs-Loeffler bacilli that he had ever met with was obtained from a mild case of diphtheria that had simulated ordinary follicular tonsillitis.

3. The degree of virulency of the Klebs-Loeffler bacilli in any given case of diphtheria is not uniform—cultures taken from the same case of diphtheria at different times during the progress of the disease develop varying degrees of virulency.

4. Clinical diphtherias characterized by the presence of the Klebs-Loeffler bacillus usually have other bacteria associated—streptococci, staphylococci, pneumococci, etc.

It has often been affirmed in that easy way that does not feel the need of proof, that "no one will deny that diphtheria is a disease due to the invasion of the body with the diphtheria bacillus, whatever influences may be necessary for the attack to be successful." This view has many faithful adherents. But Professor Biggs puts the matter thus: "The presence of diphtheria bacilli in the throat without a lesion no more constitutes diphtheria than the presence of pneumococci in saliva constitutes pneumonia, or the presence of tubercle bacilli in the nares constitutes tuberculosis. We know that in these and other infectious diseases the organisms may remain for considerable periods of time multiplying in the body cavities without entering the tissues, or producing changes or lesions of the body." And now comes the important thing to be attended to: "If," continues Doctor Biggs, "the conditions are favorable and the individual is not immune, the disease easily follows after a longer or a shorter period. But diphtheria can only be said to exist after the lesion has been produced" (communicated by letter November 24, 1900). This view seems perfectly temperate and rational; but it assumes much as being matter of fact which is only assumption and inference. Professor Biggs's view typifies the knowledge and faith of a large class of practitioners. The "favorable conditions" of this view cannot be demonstrated in any case of diphtheria. They are matters and questions of inference and assumption. Nor can the quantity and quality of any patient's immunity be foretold. This is also a question of logical inference, and not of material demonstration. "Favorable conditions" and "necessary influences" are only hypothetical phrases. They do not typify things, but only the assumed qualities of things and conditions that are not demonstrable, but scientifically imagined; and though they help us in our thinking, they are only resting places which do not by any means mark the end of the journey that must of necessity be traveled. And here we may ask, Where has the majority of the bacteriologists and many clinicians landed us? Certainly, into something more than a justifiable suspicion that the Klebs-Loeffler bacillus, as a possible or probable cause of 65 to 95 per cent. of clinical diphtherias, is of about the same status as a telling factor in the chain of events as was the stone that flew from David's sling and killed Goliath. Analogously, the Klebs-Loeffler bacillus has, as a cause of clinical diphtherias, a precedent history, just as the stone from David's sling had. But the bacteriologists know nothing of it. There's the rub! Enthusiasm in the name of science helps faith along in these matters, if only the Klebs-Loeffler bacillus has been found. The following instance illustrates what is meant: "A Willard (Mass.) parson, who had associated with a case of bacteriological diphtheria,

picked up enough of the bacilli on the clothing to infect a family several miles distant, where there had been no diphtheria in six or seven years. A case of true membranous diphtheria resulted." (Quoted by Henry L. K. Shaw, M.D., in *Albany Medical Annals*, March, 1901.) This simple uncritical narration is supposed to contain all the proof that is necessary to make it acceptable as a demonstration of the etiological significance of the Klebs-Loeffler bacillus. However, all presumptions of this kind are easily disproved by familiar experiences of an opposite kind. If Klebs-Loeffler bacilli were such infectious agents as this clear and simple Willard affair would make them, what a dreadful scourge under a blessed name health officers and medical practitioners would be! On the other hand, I am able to report two cases that prove the contrary, namely, how extremely difficult it seems to be to spread contagion by means of persons who are known to harbor virulent Klebs-Loeffler bacilli in their throats. By accident, virulent bacilli were found in the throats of one of my daughters and the chambermaid of the house. Neither of these girls had been directly exposed to diphtheria patients. At the time this occurred I was attending several cases of moderately severe diphtheria, but no Klebs-Loeffler bacilli were found in the cultures taken from my throat. For weeks Klebs-Loeffler bacilli were found in the throats of these girls, during which time they mingled in a normal way with all and everybody at home and abroad, and nobody who came in contact with them was infected or in any way suffered from diphtheria or its sequelæ. The virulence of the bacilli was tested under the direction of Professor Biggs.* The cultures were taken by me and examined by Drs. Cronk and Billings, bacteriologists to the Health Department of this city. In this connection, it may be interesting to report what one of the Health Department drivers told me the other day. During a service of four years, he never suffered from any serious throat trouble, nor had he, so far as he could remember, caused anybody to catch a sore throat or diphtheria from him, and neither had he taken any such disease home to his children. Speaking of myself, and I have heard other practitioners say the same thing of themselves, I, in the course of a twenty years' general practice, have never been the cause of carrying diphtheria from one family to another. It would be interesting to know how often Klebs-Loeffler bacilli are *not* found in the noses and throats and on the clothes of Health Department drivers and other subalterns who remove or handle infected clothing, bedding, carpets, etc., from diphtheria-infected homes, for these men fairly hug and are hugged by Klebs-Loeffler bacilli.

Not only are Klebs-Loeffler bacilli found only irregularly in cases of clinical diphtherias, and in the mouths and noses of thoroughly healthy persons, but they are also found in the nasal, buccal, and throat cavities of patients suffering from other inflammatory diseases that are not diphtheritic. Thus, in thirty-five cases of fibrinous rhinitis, Edmund Meyer† found virulent bacilli in thirteen. The course of the disease differed in no respect from that in which Klebs-Loeffler bacilli were absent or not detected. This same physician found in fifty-five cases of angina lacunaris the pseudo-bacillus in one, and the true Klebs-Loeffler bacillus in two. None of the cases showing the presence of the Klebs-Loeffler bacilli developed diphtheria symptoms or diphtheria sequelæ. Sörensen found Klebs-Loeffler bacilli in the throats of two hundred and forty cases of scarlatina but of a series of fifteen hundred consecutive cases, and in only thirty-two of the two hundred and forty cases were symptoms of clinical diphtheria noticed. Dr. J. W. Washbourne noticed the presence of Klebs-Loeffler bacilli in the nasal cavities of scarlet-fever patients, while they were absent in their throats, and no clinical signs of diphtheria developed. Such experiences make Dr. Washbourne say: "In any case, the whole subject of diphtheria of other mucous membranes than that of the fauces requires further investigation." He, like many of us, seems puzzled. In these cases there are things and conditions at work of which we have no knowledge.

Having considered some of the clinical difficulties which the Klebs-Loeffler bacillus cannot overcome, let us look at some of the difficulties peculiar to the *idea* of what constitutes a Klebs-Loeffler bacillus disease-promotor, and the difficulties that stand in the way of its being detected. E. von Behring, in his recently published book on diphtheria, does not take kindly to a number of things looked upon as important by others, concerning the special virulence of the so-called typical Klebs-Loeffler bacillus. To associate a specified quantitative virulence with a typical form of Klebs-Loeffler bacilli, he claims, is as inadmissible as it would be to adopt a special zoological norm or type of man with just such a definite amount of will-power that could expend itself only in fixed or definite operations. Other investigators, however, ascribe different degrees of virulence to specified types or forms of Klebs-Loeffler bacilli. Thus, we are told that the long or typical Klebs-Loeffler bacillus is the most virulent, and the short or club-shaped one is least virulent, or avirulent. But von Behring says he has seen long bacilli that were mild, and short ones that were quite virulent. The pseudo-bacillus is in shape like the true virulent Klebs-Loeffler; but it is avirulent, although in the opinion of Roux and Yersin it was at some time virulent. And, according to Park, bacilli that have lost their virulence are not known to have regained it. So-called xerosis bacilli also look like the true type, but are non-virulent, they having lost their power of producing toxin. Klebs-Loeffler bacilli, then, whether they be alike in form or of any form, may produce in the hands of the experimentalist much toxin or none. The microscope cannot gauge their toxicity. Inoculation tests alone can do this. Clinically we have no means of knowing beforehand who is, and who is not, immune; and, therefore, clinically we cannot tell what course the disease diphtheria will take in any particular patient, no matter what the toxic quality of the Klebs-Loeffler bacilli may be that are harbored in the respiratory cavities. The Klebs-Loeffler bacillus in the patient is a very much conditioned and unstable etiological entity at best. How much and how variously Klebs-Loeffler bacilli are dependent on certain conditions for the development of their powers is told us by Park (Bacteriology). Under certain conditions, diphtheria bacilli will grow luxuriantly without developing much toxic power. Physically, as well as conceptually, Klebs-Loeffler bacilli are loaded with many odious uncertainties. They are as inconstant after all clinical phenomena have disappeared as they are uncertain and irregular as to their forms and toxicity, and their bacteriological and pathological associations. And if we attach any importance to their presence as pathogenetic factors in the upper respiratory cavities, it will be as difficult to determine when the disease diphtheria has ceased as it is to say when it has really begun.

*According to different writers, virulent bacilli are found in from 2 to 20 per cent. of normal throats, says von Behring in his "Diphtherie." Park has reckoned that they are in about 1 per cent. of the normal throats of New Yorkers.

†*Arch. f. Laryng. u. Rh.*, IV, 2 & 3.

The routine bacteriological examinations as practised at the present time in this city do not seem to be a help in the diagnosis of clinical diphtherias, nor do they help to prevent the spread of contagion. I am speaking from the point of view of the private practitioner, and not as a hospital clinician. It was as rare in pre-bacteriological days to see recurrences of disease in afflicted families, or related families, as it is now, at least in my experience. The severest cases of clinical diphtheria are not marked by the longest and most persistent tenancy of Klebs-Loeffler bacilli. Virulent Klebs-Loeffler bacilli may persist in a singularly mild case for weeks after convalescence and recovery have become established.

Summary and Conclusions.—1. Clinically there are two kinds of diphtherias when Klebs-Loeffler bacilli are taken into account: (*a*) Those having Klebs-Loeffler bacilli present, (*b*) Those having none. Both forms, however, develop the same clinical signs and symptoms, the same complications and sequelæ—von Behring to the contrary.

2. The character or quality of the Klebs-Loeffler bacilli that may be present in any case of diphtheria does not prognosticate its course or termination.

3. Klebs-Loeffler bacillary diphtheria may be so mild as to simulate a simple tonsillitis, and yet the most virulent Klebs-Loeffler bacilli be present.

4. Virulent Klebs-Loeffler bacilli may be present in the throats of healthy people, never doing any harm to the persons harboring them, nor harming in any noticeable way or manner those who have come into close and intimate contact with the bacilli-infected people.

5. Klebs-Loeffler bacilli are found associated with other bacteria in other diseases than diphtheria, but they fail to exert any appreciable influence on the progress and decline of those diseases.

6. Klebs-Loeffler bacilli vary much in size and shape from a regular and artificially determined type, and the quantity and quality of their toxicity is not bound in any special or definite way, to fit any particular typical or atypical form, if the most recent bacteriological utterances on the subject be true.

7. The virulency or disease-promoting qualities of Klebs-Loeffler bacilli can be determined *only* by experimental inoculation tests. All that the microscope can do in this matter is to differentiate their forms; every other delivery based on microscopic investigation alone is largely guesswork or hypothetical speculation.

8. The ubiquity of Klebs-Loeffler bacilli, and their irregular and varying forms, besides the inconstancy of their toxic qualities occurring as they do with clinical phenomena that are in no determinable way to be correlated with these physical irregularities of Klebs-Loeffler bacilli, make it impossible to grant them any primary specific etiological importance in the pathogenesis of clinical diphtherias.

9. The "necessary influences" and the "favoring conditions," besides other factors of which we are still ignorant, enfold within themselves the secret of the real *causes*—not cause only—of clinical diphtherias.

10. The assumed etiological and pathogenetic supremacy of Klebs-Loeffler bacilli is largely, if not altogether, *a synthetical demonstration*. And, although this synthesis is not altogether "a bridge of fancies," enthusiastic laboratory workers and their unquestioning followers, both lay and professional, are traveling to and fro over it unhampered by any of the odious uncertainties and difficulties that have been presented in this paper. And, of course, a bridge that will not load itself with what it cannot bear will give support to any amount of "will to believe," but break under the weight of facts that it denies passage to.

359 West Thirty-fourth Street.

AN UNUSUAL CASE OF DEATH FROM ETHER ANÆSTHESIA, WITH AUTOPSY AND MICROSCOPIC STUDY.

By HARLOW BROOKS, M.D.,
NEW YORK.

Instructor in Histology and Embryology, University and Bellevu Hospital Medical College; Assistant Curator to Bellevue Hospital; Pathologist to the Montefiore Hospital for Chronic Diseases.

Death, as the direct result of a general anæsthetic, is now of infrequent occurrence. This is a very significant fact when we consider the great number of patients to whom anæsthetics are daily administered, and not uncommonly in cases of severe shock or when serious cardiac and nephritic lesions exist. That this happy condition of affairs exists is, I think, largely due to the fact that the anæsthetics furnished to the American profession are almost universally pure. We must, however, give great and just credit to the skill of those members of the profession to whom this work naturally comes. Undoubtedly, the rarity of fatal cases is also partly due to the exclusion of many of those in which contraindicating lesions are present, and to the careful selection and administration of the drug best fitted to each individual.

One cannot but feel wonder, however, at the tolerance of the vital organs, particularly of the ganglionic centers, toward the action of chemicals which produce such profound effects upon them as do the general anæsthetics, and we should not be surprised when fatalities do occur.

Nevertheless, it appears of the greatest importance to the writer that each death from this cause be studied with as great thoroughness as possible, and an account of it be placed on record where it may reach the general profession, so that as the nature of these calamities, which usually occur when least expected, becomes more thoroughly understood, they may be better guarded against.

The writer believes the following case to be of special importance, since it took place in a patient who had been thoroughly examined, without the detection of any contraindicating lesion, and to whom the drug was administered by a skilled anæsthetizer, under the most favorable conditions of a well-regulated hospital, and with all the usual means of treatment of such mishaps immediately at hand.

The patient was a man aged thirty-six years, born in the United States, and resident here for life, married, and of good habits. Previous to the receipt of the injury, he had always been in good health, and had lost no time from his work. On June 2, at 5.50 P.M., while walking across a railway track, he was struck by a trolley car, knocked down, and dragged for several feet, but did not lose consciousness. The ambulance arrived soon after the accident, and the man was attended by the ambulance surgeon, who found him perfectly rational and in but a moderate condition of shock. He had sustained a compound fracture of the right forearm near the elbow, with dislocation of the right carpus. There was considerable laceration of the muscles of the forearm, and there had been hemorrhage at the point of injury; but this was not of sufficient amount to be looked upon as a dangerous feature in the case. A temporary dressing was put on, and the patient was given ¼ gr. of morphine, hypodermically, for the purpose of quieting the pain. He reached the hospital in good condition. Here he

was given stimulants, and the wound was at once surgically cleansed. He reacted well, and when the visiting surgeon saw the case, an hour or so later, it was decided that there was no indication for immediate interference, and that it would be best to wait until morning before the injured extremity was amputated. There was but a small amount of hemorrhage, and the patient suffered very little pain during the night.

June 3, at 9 A.M., the patient was apparently in good condition; he was not suffering much pain, and the pulse was of good quality and regular. There was no fever. At 11 A.M., he was prepared for operation. Examination of the urine gave negative results, and the ordinary careful examination of the heart and lungs revealed no lesion. The anæsthetic used was the usual preparation of Squibb's ether. The drug was well taken, there being no struggling and the stage of excitement was but very slightly marked. The ether was given with the "butcher's-sleeve" cone, and plenty of air was mixed with the drug, which was administered slowly and in small quantities. The pulse was good when the ether was started, but seemed even to pick up a little more, becoming stronger apparently from the stimulation of the ether. The arm was prepared for incision, when the pulse became a little less strong, and, though no pause was made in the operative preparations, the anæsthetizer gave hypodermics of $\frac{1}{5}$ gr. of strychnine and 1 dr. of whiskey. The pulse at once responded, becoming strong and regular. About twenty minutes after the beginning of the anæsthetic, surgical anæsthesia was reached, and the operation was begun by the skin incision for the formation of the flaps. The site of operation was selected just below the elbow joint. The arm twitched a little when the skin was incised, the respirations soon became noticeably more shallow, and there were contractions of the abdominal muscles, so that the house surgeon thought that the patient was about to vomit, and told the anæsthetizer to give a little more ether; there was no cyanosis, and but a slight amount of mucus in the throat; 1 dr. of fresh ether was given and the respiration soon became more natural. The pulse was still of fair quality. Five minutes later, respiration suddenly ceased at the end of a full inspiration. There was no cyanosis, but the pupils dilated at once. The anæsthetic was immediately withdrawn, the operation stopped, rhythmic traction of the tongue instituted, the throat cleaned out, the epiglottis pulled forward, and artificial respiration begun. Whiskey, strychnine, and ether hypodermically were given, the extremities were elevated, and the sphincters were stretched, but absolutely without response; air could be forced from the lungs by the movements of artificial respiration, but apparently no involuntary or voluntary attempts at respiration could be induced, and the heart finally stopped about two or three minutes after respiration had ceased. Death probably resulted about eight minutes after the first onset of dangerous symptoms.

The anæsthetizer was a careful and reliable man of considerable experience in the administration of anæsthetics. About 4 oz. of the drug was used, and up to the immediate onset of dangerous symptoms the patient was thought to be taking the ether even more than ordinarily well.

Autopsy.—The following is a report of the autopsy held June 3, 1900, nine hours after death:

"The body was that of a well-formed mulatto male. Rigor mortis is general, but still increasing, and there is yet some animal heat in the body. The tibial borders are free. The hair is slightly gray.

"The skin covering the lower two-thirds of the right forearm is completely removed, together with the subcutaneous tissues down to the muscle fascia. There is a compound dislocation of the carpus, and a laceration of the tissues at internal condyle, exposing the elbow-joint which has been partly separated. The cartilages of the ulna and humerus have been slightly bruised, and the muscles of the ulnar side of the forearm are considerably lacerated. There are two small abrasions of the epidermis over the right forearm. There is also an abrasion of the skin measuring four by two centimeters over the ulnar surface of the left forearm; otherwise there are no marks of violence.

"The general musculature is unusually well developed, especially that of the extremities. There is a normally abundant light-colored deposit of subcutaneous fat.

"There are dense old adhesions to the anterior thoracic wall, and chronic adhesions partially obliterate both pleural cavities; but they are not of sufficient extent, and are so stretched that they probably did not retard respiratory movements. The exposed pericardium is large. The pericardial sac contains a natural amount of fluid, and it is normal, except that perhaps the venous capillaries are somewhat overcongested. The heart is enlarged. The left ventricle is firmly contracted, but not abnormally so. It contains a small amount of post-mortem clot and a small quantity of fluid blood. The right ventricle is also somewhat contracted and contains a small mass of mixed clot. The right auricle is relaxed. The left auricle shows a thickened endocardium and is moderately dilated. The aortic segments are thickened, but perfectly functional. The conus arteriosus is of rather small caliber, measuring about 5.5 cm. in circumference. Its intima and that of the coronary arteries is quite generally thickened, and higher up in the arch is a progressive insular sclerosis. The mitral segments are quite generally thickened, and the middle segment shows a small calcareous nodule on the posterior surface near its attachment. The heart muscle is firm, there is no fatty infiltration or degeneration, but the vessels are surrounded by thickened connective tissue, and in places, especially in the papillary muscle of the mitral valve, there is a moderate fibroid myocarditis. There is no relative incompetence of the valves and no evidence of acute dilation, except in the condition of the auricles above mentioned.

"The tongue is normal except that the lymph nodes on its dorsum are considerably enlarged. The lymphatic structures of the pharynx are chronically hypertrophied; otherwise that organ is natural. The œsophagus is normal. The arch of the aorta shows arteriosclerosis of quite a pronounced degree, and in places extensive excavation of the intima has resulted; no strictly acute areas are to be seen, however, and the condition does not extend into the carotids or subclavians, which are but very moderately diseased. Small nodules of thymus tissue are still present. The lymph nodes of the neck are slightly enlarged and anthracotic. One contains a small calcareous nodule, apparently the result of anthracosis. The thyroid gland is small; it is natural in structure. The epiglottis is elongated, but is natural.

"The rima glottidis is sufficiently open, and there is no œdema or congestion of the mucous membranes, either of the larynx, trachea, or large bronchi. The large bronchi contain a moderate amount of frothy mucus, but none is present in the trachea or larynx. The lungs are not congested, and are but slightly œdematous. They show a moderate lymphatic anthracosis.

"There are dense old adhesions in the region of the

spleen. This organ is moderately enlarged, but the tissue is normal in appearance. The liver is of natural size; its tissue is firm; the markings are rather indistinct. Apparently there is a very moderate fatty degeneration, but not more than ordinarily found. The gall-bladder contains about 15 c.c. of greenish bile. The duct is open. Weight of the liver is about three pounds. The omentum is long and fairly rich in fat; it is bound to the caput coli by a few old adhesions. The appendix is long; it lies posterior to the caput, to which it is attached by slight adhesions. The lymph glands of the mesentery and of the retroperitoneal chain are not enlarged. The peritoneum is normal throughout. The stomach is small and flaccid. Its mucous membrane is natural. The duodenum contains a small amount of well-mixed and digested food; a similar material is found in the lower bowel in a more advanced stage of digestion, but in small quantity. The entire intestinal canal shows no abnormality. The pancreas is normal in size, and its tissue is normal. The suprarenal bodies are small; their substance is apparently normal.

"The kidneys are somewhat smaller than usual. The capsules are not adherent. The markings are distinct. The cortex is thin but regular. There is a moderate general interstitial increase. Apparently interstitial hyperplasia is present, yet of slight extent. The blood vessels are not congested, nor is the tissue œdematous. The parenchyma is apparently in good condition. The bladder is natural, with the exception that the urachus is still perforated for about 2 cm. above the fundus. The seminal vesicles and prostate are normal. The large blood vessels of the abdomen show moderate arteriosclerosis.

"The skull cap is small and well arched. The arching is deeper on the right than on the left. There is very little cancellous bone between the plates, which are thick and heavy. The superior longitudinal sinus is normal; the sinuses at the base are also normal, and contain a small quantity of fluid blood. The pituitary body is small and apparently normal. The dura mater is normal. There is a moderate amount of œdema of the piaarachnoid, which is most abundant, over the vertex. The venous radicals of the piaarachnoid are moderately injected, and there are a few areas of opalescence to be seen along the tracts of the blood vessels. The cerebrum is symmetrically formed. The convolutions are large and fairly typical, and the sulci are deep. The large blood vessels of the base are in a natural condition so far as can be seen. The cortical layer of gray matter is thick and regular. The basal ganglia show no gross abnormality. The cerebellum and medulla are apparently normal. (Lesions in the floor of the fourth ventricle were especially sought for.) No gross lesion is present in the upper cervical cord, nor in any of the nerve centers examined. Fat embolus is nowhere present. There is no gross lesion present which accounts for death."

After removal from the body, the tissues were placed in 95 per cent. alcohol, and when sufficiently hardened they were imbedded in paraffin, after the usual method, and sectioned.

Microscopical Examination. — "Heart. — The amount of endomysium is augmented; apparently the hyperplasia has originated from proliferation of the perivascular interstitium, for the most part. The hyperplastic connective tissue is mostly of an adult form, though occasional patches are more highly cellular and show evidences of recent proliferation. The blood vessels, even to the smaller arterioles, show a marked increase in the subendothelial connective-tissue layer; with but few exceptions, however, there are no evidences of recent hyperplasia. The size of the cells varies considerably. Cross striation is normally evident and in transverse sections the ends of the sarcous elements are plainly seen. The cell nuclei are considerably altered; they are often proportionately too large for the cytoplasm which surrounds them, eccentric in location, and of many fantastic shapes, some of which show faulty karyokinetic figures. In many places, both cells and nuclei are apparently natural in every respect.

"Lungs.—Sections of the lung show nothing not already indicated in the gross examination, with the exception of a chronic subendothelial arteritis of a moderate degree.

"Liver.—The stroma shows a slight hyperplasia of a chronic character. The blood vessels here seem less involved than in the other parts mentioned. The portal capillaries are not congested. The liver cells are practically normal, though some of them perhaps contain more than a natural quantity of oil globules.

"Kidneys.—There is a slight connective-tissue overgrowth of less extent than was supposed from the gross examination. The cells of the parenchyma are generally intact, though some show a considerable fatty degeneration, and the cytoplasm has broken down in a few places, to a greater or less degree. Occasional cells contain quantities of coarse brown pigment; this is most frequent and most marked in cells lining the straight collecting tubules, though some of the cells of the convoluted tubules also show the change. The vessels of the kidney show a moderate degree of subendothelial hyperplasia.

"Adrenal Bodies.—The adrenal bodies show nothing abnormal.

"Encephalon.—The blood vessels of the cerebrum, cerebellum, and those found along the floor of the fourth ventricle show slight atheromatous changes, certainly not enough to act as a seriously predisposing factor toward rupture or blood extravasation. A very careful gross and microscopical examination for such lesion was without result. The external layer of the cortex seems somewhat macerated, probably from the superabundant meningeal fluid. The cortical archochromes and archostichochromes of the cerebrum (left paracentral lobule) occasionally show the nuclei faintly stained. Not infrequently the cytoplasm contains considerable clumps of coarse brown pigment; this is the most common lesion observed. In most of the cells the chromatic substance is normally arranged and reacts properly to the Nissl dye. There is no chromophilia, either of cytoplasm or nucleus, and by far the larger number of cells are absolutely normal in appearance. The cortical stichochromes from the same place show pigmentary changes even more frequently than do the cells just considered. In the stichochromes the pigment mass is usually situated below the nucleus in the base of the cell; the granules are large and of quite regular size; sometimes where the cell has been pressed upon by the cover-slip, these granules have been more or less separated, showing that they are distinct, well-defined bodies. In most cases the chromatic substance is normally arranged, well colored, and can be demonstrated well out into the cell processes. Occasional cells show but a faint reaction to the dye, sometimes only part of the chromatic substance staining, in which case it is usually the spindles nearest the nucleus which stain most faintly. A few of these cells show the chromatic substance distributed throughout the cytoplasm as rather coarse spheres, apparently suspended on a faintly colored or colorless network, and without apparent

relation to the chromatic spindles normally present. This variation is uncommon, and is generally associated with rather an indistinct line of demarkation between the nucleus and cytoplasm. Two or three cells are found which show a fine subdivision of the chromatic spindles; in these instances, the picture may be an artefact, and may have been caused by crushing the cell from the pressure of the cover-slip. The nuclei in nearly all the cells present no obvious peculiarity. The Purkinje cells of the cerebellum are, as a rule, rich in chromatic substance, the spindles being closely pressed together and arranged in planes surrounding the nucleus. The chromatic network is plainly evident in most of the cells. All the Nissl plaques have stained deeply, a few show a somewhat granular separation of the chromatic spindles; but nearly all these cells are beyond question normal. The ganglion cells found along the floor of the fourth ventricle, as a general thing, are normal, in so far as I could determine; some show a quite marked granular disintegration of the chromatic bodies, and in others the chromatic elements were clumped together in masses of considerable size. A pigment deposit similar to that described in the cells of the cerebrum is also present in these cells."

Conclusions.—The absence of congestion of the lungs, of obstructing bodies in the air-passages, and of all evidences of cyanosis would indicate that the cause of death was other than from respiratory obstruction, which is the factor most frequently reported by operators as occurring in ether anæsthesia.

The animal experiments of Lindermann of Moscow have shown that invariably, when death results from too prolonged ether anæsthesia or from the drug being administered in too great concentration, congestion and œdema of the lungs are present. The absence of these alterations, as well as the history of the case, would then exclude these most common conditions.

In brief, the lesions found in the case may be stated as:

I. A compound fracture of the forearm, which exposed the wrist and elbow joints, accompanied by rather extensive laceration of the muscles of that member.

II. Interstitial myocarditis of moderate degree, complicating functional cardiac hypertrophy.

III. Chronic arteriosclerosis of marked degree in the aorta, but not extending to the smaller vessels, excepting those of the heart.

IV. Submeningeal œdema of slight extent, limited to the cerebral vertex.

V. Pigmentation of the ganglion cells of the cerebral cortex and a similar condition of the cells along the floor of the fourth ventricle. Slight and occasional degenerative changes in the cytoplasm of these same cells.

It does not seem at all probable that the cause of death was shock, for symptoms of this condition were lacking when the anæsthetic was started; and, furthermore, the extent of the traumatism did not seem sufficient to have caused so serious a condition of shock in an otherwise healthy man.

From the history of the case and from the absence of general vascular disease we are led to conclude that the cardiac and aortic disease was probably the result of over-function, and the previous history of the man, who had always performed heavy labor, bears out this supposition. Of course, the lesions of the heart, under the conditions prevailing, could not ordinarily have been determined by the methods of physical diagnosis, which could detect only an increased area of cardiac dulness. Were it not that respiration ceased absolutely about two or three minutes before the heart stopped, we would infer that the cause of death was the action of the drug on the heart ganglia or muscle—a rather unusual method of death in ether anæsthesia, it is true, and absolutely excluded in this case.

I believe that the somewhat minute examination precludes the possibility of embolus of a vessel of a vital center.

Such slight submeningeal œdema as was found could not have caused death, and probably did not even act as a factor in its causation; for it is a condition very commonly found, and when of such slight extent is probably without pathological significance.

The alterations found in the nerve cells were plainly not of recent production, and they were of slight extent. The pigmentation is not usually considered as a strictly pathological state, though I believe it is rarely so abundant in young adults as was the case in this instance.

Admitting, as I believe we must, that the cause of death was the action of the drug on the ganglion cells of the respiratory center, I doubt very much if an effect so quickly produced as in this case would leave in the nerve cells any morphological lesion evident by our present methods of examination.

PRACTICAL RESULTS WITH ONE THOUSAND CASES OF NITROUS OXIDE AND ETHER NARCOSIS.*

By H. W. CARTER, M.D.
NEW YORK

So much has been written upon the subject of nitrous oxide and ether anæsthesia, and the method is now so well understood and its merits so greatly appreciated by the leading surgeons and general practitioners of this country, that a description of it at the present time is not necessary. (See MEDICAL RECORD, April 14, 1900.)

In this paper, with your kind indulgence, I shall briefly touch upon the physiological action of nitrous oxide and ether as compared with chloroform, pointing out some of the advantages of their use in combination and the results which are thereby obtained.

That nitrous oxide and its modifications with oxygen gas or air are the safest general anæsthetic we possess is a fact, I think, which no one will deny. Practically, the only danger associated with its administration is asphyxia, for cardiac complications are exceedingly rare, and are usually secondary to the lulling to sleep of the respiratory center. That this so-called gas asphyxia is not due to nitrous oxide, but to the concurrent deprivation of atmospheric air, and that it has of itself specific anæsthetic properties, is proven by the fact that, with the admixture of oxygen in proper proportions, anæsthesia can be induced and maintained indefinitely without any symptoms of asphyxia whatever.

It is, therefore, of the greatest importance in administering nitrous oxide to keep a close watch upon the respiration, and to admit air with the first sign of impending suffocation. Anæmic persons, and children especially, sometimes become asphyxiated very quickly under nitrous oxide, even when small quantities of the gas have been used, and it is perfectly possible to kill one of these patients with the amount ordinarily used as a preliminary to ether narcosis, unless the color and respiration are carefully watched and plenty of air admitted.

Indeed, I have often been surprised at the very small quantity some of these patients actually require, and the degree of dilution with air they will tolerate.

* Read before the Section on Surgery of the New York Academy of Medicine October 11, 1901.

without interfering with the rapid and pleasant induction of anæsthesia.

On the other hand, plethoric and robust patients, and alcoholics especially, frequently require a considerable increase over the quantity ordinarily used in order to induce a narcosis free from the disagreeable sensations of ether inhalation. This can always be accomplished by judiciously admitting air, and I seldom find it necessary to allow more than a slight degree of cyanosis to develop in these cases. This is of short duration and does no harm, provided the respirations are full, regular, and unimpeded. In this connection it would be well to note that the respiration is always more or less interrupted if the ether is turned on before unconsciousness supervenes, or the strength of the vapor is too rapidly increased.

In cigarette smokers, or persons suffering from chronic laryngitis, in whom there is hyperæsthesia of the respiratory mucous membrane, it is sometimes necessary to proceed with the greatest caution, as the cough frequently excited in these cases may seriously embarrass respiration.

During an ordinary nitrous-oxide inhalation, the respirations are at first quickened and increased in depth; but, as the narcosis deepens, they become slowed and shallow, and if the gas be pushed, a complete cessation of respiratory movements will eventually take place (Buxton).

In the first and second stages of narcosis, the heart beats quietly, fully, and regularly, but as the anæsthesia grows more profound with the approach of stertorous respiration and other phenomena of asphyxia, the pulse becomes small, hard, and slightly accelerated. The blood pressure is also somewhat lowered, but this is due more to dilatation of the superficial capillaries and the vessels of the brain and spinal cord than to direct cardiac or vasomotor depression.

During profound anæsthesia, the vessels of the kidneys are contracted and the secretion of the urine is diminished, and it is claimed by some that the administration is occasionally followed by diabetes; but upon this point the evidence is somewhat lacking.

The main advantages of nitrous oxide as a preliminary to ether are its almost perfect safety and its rapid and pleasant action, while the principal disadvantages of ether are its disagreeable pungent odor, its irritability to the respiratory mucous membrane, and the slowness of the onset of anæsthesia.

In using the two in combination or succession, the pleasant and rapid action of the gas supplants the prolonged disagreeable sensations of the first stage of ether inhalation, the patient entering almost directly into the state of full surgical narcosis. This is accomplished with very small quantities of the two agents, and the saturation of the blood and tissues with ether is thus avoided.

Having considered the physiological action of nitrous oxide somewhat in detail, I will now briefly discuss the action of ether upon the principal functions of the body, viz., the respiration, circulation, and organs of excretion.

Because ether has a strong, pungent odor, and is very irritating to the respiratory mucous membrane when breathed in a concentrated vapor, it is commonly supposed by those whose experience with this agent is limited that all the bronchitis, pneumonia, and œdema of the lungs following its administration are due to the anæsthetic.

That this is not true, but that such complications are exceedingly rare when ether is properly administered, and the quantity used is restricted to the smallest amount consistent with good anæsthesia and the requirements of the surgeon, is attested by every anæsthetist who has had a large experience in the administration of anæsthetics. Among the contributing causes of pulmonary complications following the administration of ether may be mentioned: (1) Intestinal obstruction with fecal vomiting, the contents of the intestines being sucked up into the bronchial tubes causing septic pneumonia; (2) The nature of the operation, such as removal of cancer of the tongue, the opening of post-pharyngeal abscesses, etc.; (3) The pre-existence of coryza, bronchitis, pleurisy, or some form of pulmonary disease. (4) The loosening and drawing into the bronchial tubes of dried secretions and incrustations from the nasal cavities, and the aspiration of mucus and saliva from the mouth and pharynx, which is the home of the pneumococcus of pneumonia. I believe this is a strong predisposing cause of septic pneumonia and bronchitis, following the administration of anæsthetics to people of lowered vitality and uncleanly habits, whose teeth from long-continued neglect are laden with the products of decayed and decomposing food-particles. (5) The lowering of bodily temperature and exposure during and after operation. (6) Faulty administration, the patient being crowded from first to last with an excessive amount of ether, until his lungs and blood are overcharged with the anæsthetic, leading primarily to asphyxia and œdema of the lungs, and, secondarily, to bronchitis or pneumonia. There can be no question that were the same care and caution generally exercised in the administration of ether as is universally the case with chloroform, there would be fewer accidents and less prejudice against its use on the part of patients.

Upon the respiratory center, ether acts as a powerful stimulant; but, like all stimulants, if carried too far, it depresses, and finally arrests respiration by directly paralyzing the respiratory center. Locally, it acts upon the nerve terminals of the respiratory mucous membrane as an irritant, sometimes causing profuse bronchorrhœa.

The moist râles frequently heard in the throat during etherization, however, are very seldom due to a true bronchorrhœa, but to aspiration back and forth into the larynx of the saliva and mucus, which, lying loose around the glottis, becomes churned into a tenacious white froth, and impedes the free entrance of air into the lungs. In its action on the heart lies the great safety of ether as a general anæsthetic. On this organ it acts as a powerful stimulant, and the stimulation usually persists to the end of a long operation. Unlike what happens under chloroform, when the heart does begin to fail, it goes down slowly and gives plenty of warning of impending danger.

The inhalation of ether is accompanied by a great rise in the blood pressure, and by dilatation of the superficial capillaries and the vessels of the head and brain. This is evidenced by the flushed face and the profuse diaphoresis observed during the administration, and the fact that the centers governing respiration and circulation are fully supplied with blood adds greatly to its safety, as cardiac or respiratory syncope occurring during anæsthesia is oftentimes due to anæmia of the vital centers of the medulla oblongata.

Dr. Simon P. Kramer has shown by experiments upon etherized dogs (*Annals of Surgery*, September, 1900) that irritation of the central end of the divided crural nerve produces no effect if the animal is deeply narcotized, but that, if a condition of semi-anæsthesia exists, the respiration becomes greatly accelerated in rhythm and increased in amplitude, while there is a marked fall in blood pressure.

This vasomotor shock and reflex inhibition of the heart's action is an element of great danger at all times under incomplete chloroform anæsthesia, as it adds to the cardiac and vasomotor depression of

chloroform, while the accelerated respiration increases the liability to an overdose of the concentrated vapor, which, reaching the heart through the coronary arteries, may cause direct cardiac paralysis.

In ether anæsthesia, on the other hand, since the heart is stimulated and there is a great rise in blood pressure, the vital centers of the medulla oblongata being well supplied with arterial blood, this respiratory reflex becomes one of the most valuable guides in conducting a light narcosis. The action of ether upon the kidneys is that of an irritant; but clinical experience teaches us that healthy kidneys are but little affected by this drug when administered properly, and the dose is not excessive.

Quantity for quantity, it is well known that chloroform is far more irritating to the kidneys than is ether; but the small amount of chloroform necessary to induce and maintain narcosis, and the excessively large doses of ether which, with the use of crude methods and untrained anæsthetists, it has been the custom in the past to use, it is no wonder that an occasional temporary nephritis with albuminuria and diminution, or even with total suppresion of urine, followed its administration.

Drs. W. H. Thompson and Robert Coleman Kemp have shown by elaborate experiments upon dogs that ether always causes a diminution in the amount of urine secreted during the inhalation, and sometimes an absolute suppression with marked albuminuria. There is, however, a vast difference between the results of their experiments and those of clinical observation. Moreover, the diminution or suppression of urine during the time of the inhalation of ether is no evidence that the administration will be followed by any permanent or even temporary impairment of the secretory functions of the kidneys. Granting that Thompson's and Kemp's experiments have conclusively shown that ether does cause diminution or suppression of urine during inhalation, clinical experience abundantly proves that this effect ceases with the administration in practically every case.

The fact that ether stimulates every secretion of the body except that of the urine, and that it causes a marked dilatation of the superficial capillaries and profuse diaphoresis, with consequent temporary reduction of the volume of the blood plasma, would alone account for this diminution. Thus, more fluid and excretory products may be eliminated during the administration of ether than would be otherwise, and this in spite of the fact that there is an actual diminution in the urinary secretion.

Provided it does not excite nausea and vomiting, water should be given freely both before and after etherization, since it tends, on the one hand, to restore the normal volume of blood plasma, which has been reduced by catharsis or other preparatory measures, and, on the other, to assist in the rapid elimination of the drug. Nephritis, following the administration of ether, is, in my opinion, more often due to exposure during the operation or to an excessive amount of the anæsthetic than to the irritation upon the renal epithelium of a therapeutic dose skilfully administered.

In a large experience in the administration of ether, both alone and in succession to nitrous oxide and chloroform, I have never had, to my knowledge, a single case of severe or persistent albuminuria, bronchitis, pneumonia, or other serious renal or pulmonary complication.

In view of the fact that chloroform is a powerful protoplasm poison, and that in equal quantity it is far more irritating to the kidneys than ether, it becomes a question in my mind that if the quantity of ether inhaled could be reduced to something near the amount of chloroform required, whether it would not be safer in mild cases of albuminuria to administer ether in preference to chloroform.

In administering chloroform to patients with diseased kidneys, more attention should be paid to the secondary results of renal inadequacy, for there is every reason for believing that uræmic conditions so impair the vitality of the tissue elements as to leave the system in the worst possible condition to resist the ravages of chloroform inhalation.

I find the number of patients who cannot take gas and ether to be exceedingly small. Even alcoholics and drug habitués, in whom the system has acquired a marked tolerance for narcotics of all kinds, and who are particularly hard to anæsthetize, the nitrous oxide, by inducing unconsciousness with primary anæsthesia, enables the full strength of the ether vapor to impinge upon the respiratory mucous membrane and the stage of surgical narcosis to be quickly reached.

In some cases, however, it is unquestionably better to use chloroform. I consider it a good plan at such times, unless there are special contraindications, to induce complete surgical narcosis with gas and ether and to continue the administration with chloroform.

The stimulation of ether preceding the depression of chloroform is a great advantage, as it fortifies the vital centers of the medulla: the chloroform narcosis beginning with a stimulated heart and an increased blood pressure, while the dangers of primary anæsthesia are almost entirely avoided.

The logic of this argument can be readily appreciated by reviewing the statistics of chloroform anæsthesia, which show that in more than 50 per cent. of the mortality, death, whether due to cardiac or respiratory paralysis, occurred during primary anæsthesia, and when only a small quantity of the drug had been taken, the heart and vital centers, as it were, being taken by surprise and rapidly overcome by the depressing influence of the chloroform vapor.

In neurotic patients and children, the method is particularly valuable, since their nervous fears are allayed and confidence inspired by the pleasant nature of the inhalation, while the rapid action of the gas quickly produces unconsciousness. In valvular diseases of the heart, provided there is good compensation, nitrous oxide and ether can be administered with almost perfect safety, as the quantity of gas required is small, all air is not excluded, and the heart quickly receives the benefit of ether stimulation.

Old people take gas and ether particularly well, but in these especial care should be exerted and its use avoided in all cases of arterial degeneration.

In all pulmonary diseases, provided the heart is not affected, I would advise the use of chloroform in preference to gas and ether, though mild cases do not contraindicate the use of nitrous oxide.

The advantages of nitrous oxide and ether over other anæsthetics are many, and it is gratifying to know that the method is rapidly growing in favor. Its only disadvantage is that it requires somewhat complicated and expensive apparatus and considerable skill to use it successfully.

Its general adoption would necessarily lead to the systematic instruction of anæsthetics, and would make of every hospital interne an expert anæsthetist.

Wholesome Meat.—To-day, the least we must admit is that the flesh of tuberculous cattle is not as harmless as Professor Koch pretends. My intention is not to discuss at length this new theory, but I will be permitted to state that, generally speaking, it is not safe to partake of meat not absolutely healthy. In following certain rules, we may at least avoid poisoning by ptomaines, if not tuberculosis.—Dr. L. Laura (*Mag. Prosmectic*), Turin.

Ureteral Catheterism in the Male; A New Ureter-Cystoscope.—Bransford Lewis describes his cystoscope, whose freedom from complexity, he claims, relieves it of many of the sources of difficulty encountered in the use of the older forms. It consists of a tube which carries in its upper wall a smaller tube for the conduction of the wires that connect with an electric lamp, and in its lower wall another small tube for the conduction of the silk-web ureteral catheter, and for guiding and controlling its inner extremity after it reaches the bladder cavity. The light from the lamp emerges through a glass window, sealed in the roof of the main tube. The lamp affords a brilliant glow, but radiates so little heat that it may be held within a quarter inch of live tissue for an indefinite period, and without pain or even discomfort. It can be used with perfect safety and comfort so far as heat is concerned in the *empty* bladder. Thus, the use of fluid is eliminated, together with its several disadvantages, such as rapid clouding by in-flowing pus or blood, etc. There are no lenses to intervene between the eye and the object of investigation. The window is so placed that, should it become smeared with pus or blood, it may be cleansed by a cotton swab without removal from the bladder. The lamp is brought within half an inch of the membranes being searched, which is of great advantage.—*St. Louis Courier of Medicine.*

The Stereognostic Sense.—L. Harrison Mettler defines this sense as the faculty by which we determine the size and character of objects held in the hand. It is sometimes lost in disease, as in late tabes, and should be tested in every case of suspected sensory disturbance. It is an exceedingly complicated perceptive phenomenon, possibly involving, as Sidler suggests "an intricate correlation of tactile, position, localization, and pressure perceptions." Astereognosis can hardly be considered a very definite localizing symptom. Its presence would indicate merely a break in the peripheral tactile paths or in the central associative areas, where the numerous inpouring impulses are brought into comparison with one another. Astereognosis will indicate merely a false perception (psychosis) resulting from an alteration in the central perceptive apparatus, or in the paths that connect this central apparatus with the peripheral organs of touch (neurosis) found in the skin, muscles, tendons, ligaments, etc. While in itself, therefore, it does not promise much as a very definite localizing symptom, in conjunction with other symptoms it may prove to be of the greatest value.—*Medicine.*

The Steatolytic Ferment of the Stomach.—F. Volhard, in continuing his investigations of the fat-splitting enzyme discovered by him in the stomach, found that remarkable differences exist between the product obtained from the gastric mucosa and from the juice itself. Alkalis act powerfully in the ferment from the juice, while a glycerin extract of the mucous membrane is far more resistant; but, on the other hand, when obtained from the gastric juice, this body is much less susceptible to the action of hydrochloric acid than when it has been prepared from the tissue. A further conclusion is that the gastric juice contains the ferment itself, while the zymogen is found in the mucous-membrane extract. Steatolysis in the stomach goes on irregularly and is incomplete, and independently of the amount of neutral salt present, only a certain percentage of it is split up. In achylia, the secretion of the fat-splitting ferment, like that of pepsin and rennin, is greatly reduced, while high grades of hyperacidity inhibit steatolysis in the stomach.—*Zeitschrift fur klinische Medicin.*

Streptothrical Infections.—John H. Musser notes that we have been familiar for some time with two streptothrical infections—actinomycosis and the disease known as Madura foot. He believes that we are liable to meet other forms of this infection, and reports two cases of much interest. The first case was that of a man of thirty-seven years, with physical signs of bronchitis and dilated heart. Bronchopneumonia later developed, and death ensued from exhaustion due to the cardiac condition and œdema of the lungs. The sputa revealed the presence of a streptothrix. Musser states that it may have been either a primary infection or one secondary to a streptococcus infection of the bronchial tract. He says also that we must bear in mind the possibility of such organisms being branched forms of the tubercle bacillus. The second case was that of a man of twenty-four years with symptoms suggesting meningitis. On autopsy, a brain abscess was found, the pus being very offensive and containing a streptothrix.—*St. Louis Medical and Surgical Journal.*

The Staff Surgeon-General of the German Army.—Surgeon-General Rudolf Ferdinand von Leuthold, First Physician-in-Ordinary to the German Emperor, has been appointed Staff Surgeon-General of the German Army in succession to the late Surgeon-General von Coler. Surgeon-General von Leuthold, says the *British Medical Journal*, was a pupil of the Friedrich Wilhelm Institute, and received his professional education at the University of Berlin. After passing the State examination in 1857, he became an Assistant Surgeon in the Medical Department of the Army, rising to be Staff Surgeon in 1862, Staff Surgeon-Major of the second class in 1867, Staff Surgeon-Major of the first class in 1875, and Surgeon-General in 1889. He was associated with the late Professor von Lauer in the medical care of the Emperor William I., and on the accession of the present Emperor was chosen by him to be his Physician-in-Ordinary. Surgeon-General von Leuthold was for many years professor of military surgery in the Kaiser Wilhelm Academie, and was at the same time editor of the *Deutsche militairarztliche Zeitschrift.*

The Relations of Human and Bovine Tuberculosis.—Schwalbe relates an instance in which, in spite of a herd of highly bred cattle, kept by a gentleman farmer under the best possible hygienic conditions, developed tuberculosis shortly after a consumptive stableman was engaged. After an analysis of this and several similar cases, he comes to the conclusion that human tuberculosis plays a very important rôle in the etiology of the disease in domestic animals, especially in cattle. This source of infection has received but little attention, but deserves careful consideration and study at the hands of both physicians and veterinarians. Tuberculous cattle cough and expectorate so little that in well-conducted dairies the main source of infection cannot lie in this direction, while the presence of consumptives in stables involves so great a risk to the animals that none such should be allowed to come in contact with them.—*Zeitschrift fur Tuberkulose und Heilstattenwesen.*

The Present State of Our Knowledge of Autointoxication.—J. Kovacs believes that in such cases there is a great increase in the osmotic pressure of the blood. The materials leading to autotoxicity are permanently present in the system, but why they are in one case active and in another absolutely inactive is not easily explained. The explanation may be, first, that these chemical products being very changeable are decomposed, and later on unite with other products of metabolism, and in such way they are harmless; secondly, that the organism has under its command certain bodies that defend it, which hold the enemy in check, and so these poisons are eliminated from the organism. Experiments have shown that in diseases in the course of which autointoxication occurred in its most striking form, the osmotic pressure of the blood was increased to the highest point.—*Medical Press and Circular.*

Report of Twelve Cases of Surgical Intervention in Tuberculous Peritonitis.—Alfredo Ramoni reports twelve cases of laparotomy for tuberculous peritonitis. Of the number seven patients recovered, and are still in good

health after a lapse of three or four years. Two have escaped observation. The operation in each case consisted in a median incision of the abdominal walls below the umbilicus to an extent of from 5 to 8 cm., a buttonhole into the peritoneal cavity, and gradual emptying of the ascitic fluid, followed by drying of the cavity by means of boiled gauze, and finally complete closure of the wound in three layers. The author is decidedly in favor of surgical intervention, spontaneous cures being altogether exceptional, and medical treatment of slight avail.—*Gazette Medica di Roma.*

The Medical Treatment in Surgical Tuberculosis.—W. B. Thistle says that tuberculous cases requiring surgical treatment in the great majority of instances receive no medical treatment, surgeons, as a rule, being content with purely mechanical treatment. He urges the application of climatic and hygienic measures, as in cases of pulmonary tuberculosis, and the administration of drugs which improve nutrition, and which weaken the power of the tuberculous germs. For the first purpose, iron, arsenic, and strychnine have gained the greatest repute, but must be given continuously and for long periods. For the second purpose, Dr. Coghill has found that by saturating the body of an animal with creosote, it could be rendered immune to tubercular infection, and if the animal were already infected, the growth of the tubercle could be largely inhibited. In a human being, twenty to thirty minims three times a day brings about the necessary degree of saturation. Creosote, unfortunately, is an irritant, but this property may be counteracted by means of bismuth. The author's plan is to order creosote in bulk, say one ounce, and to order a quantity of bismuth subnitrate. The patient loosely fills a capsule with bismuth, and then drops in slowly as much of the creosote as will be absorbed by the bismuth. As many capsules as are needed to contain the dose may be filled. The creosote should be taken three-quarters of an hour after meals, beginning, say, with five minims, and gradually increasing to from twenty to forty drops three times a day. The results are excellent, and often remarkable.—*The Canadian Practitioner and Review.*

A Review of Some Recent Literature on the Etiology of Carcinoma.—Aloysius O. J. Kelly calls attention to the fact that has been pointed out by Sailer that Schaudinn, one of the keenest zoologists, has lately stated that he has carefully examined sections of one hundred malignant growths in which the so-called parasites were present, and he is convinced that the growths did not contain any bodies that could be regarded as coccidia or protozoa. The writer is not willing to deny that malignant tumors may be due to the pathogenic activities of lower forms of life, still he believes that the proposition has not yet been proved, and that there are many facts known that speak against the likelihood of its ever being proved, at least with the present methods of investigation. He concludes by quoting Ziegler's opinion: "The formations that have been described as protozoa and blastomycetes are in reality degenerated nuclei, degenerated nucleolar figures, various products of the cell protoplasm, such as mucus, colloid, hyalin, keratohyalin, or cells; for instance, cancer cells that have included leucocytes or the products of their retrograde metamorphoses. The supporters of the parasitic theory of tumors are in reality decreasing in number, and this phenomenon is justified not only on account of the want of the demonstration of the occurrence of tumor parasites, but also because all the biological characteristics of tumors speak against their parasitic nature."—*University of Pennsylvania Medical Bulletin.*

The Treatment of Tuberculous Peritonitis.—R. Humphrey Martin considers that we can get good results in this disease by either medical or surgical means. Dr. Yeo pleads for the former, which consists of rubbing into the abdomen three times a day a liniment consisting of equal parts of cod-liver oil and iodoform ointment (1 in 10). He also gives a pill containing ¼ grain of iodoform with ½ minim of creosote three times a day. All practitioners would probably prefer to give this treatment a trial for at least six weeks. As to surgical treatment, Watson Cheyne thinks that 50 per cent. can be cured, the prognosis being most favorable in the ascitic variety, next so in the fibro-adhesive form, and least in the ulcerous variety. In all chronic cases which have lasted from four to six months, laparotomy should be performed, the operator simply opening the cavity, draining off any fluid present, and immediately sewing up the wound. There is no satisfactory explanation of what brings about the cure, but it has generally been thought to be due to the admission of daylight. Aspiration alone, or aspiration followed by the pumping in of air, does no good; but let in air and light, and in a few months the peritoneum, on being reopened, will be found to be quite free from any sign of tuberculosis.—*The Australasian Medical Gazette.*

On the Value of Iodine Cataphoresis in the Treatment of Hypertrophy of the Thyroid Gland.—Jacopo Nardi has had good success by means of this treatment. His method consists in soaking a bit of cotton in an alcoholic solution of the tincture of iodine, applying it to various parts of the hypertrophied gland, and placing on it the anode. The cathode may be placed on the back of the neck or the palm of the hand. As a rule, fifteen to twenty milliamperes may be applied for from ten minutes, as a minimum, to forty minutes, as a maximum. The efficacy of this form of treatment is in direct relation to the softness of the glandular tissues, being of little value where fibrous degeneration is at all extensive. It is of no use at all in cases of cystic struma. Improvement, when it occurs, is at first rapid, and then somewhat slower.—*Giornale Internazionale delle Scienze Mediche.*

A Fatal Case of Acute Dermatitis Exfoliativa.—E. Brunsgaard describes a case occurring in a boy of seventeen years. In the subcutaneous tissues were found numerous effusions of blood containing diplococci and streptococci, and certain agglomerated cocci stained by Gram's reagent. The clinical symptoms and post-mortem findings pointed to a general infection; the skin affection is probably an expression of this infection, but one which forms the characteristic and essential feature of the disease. It was not possible in this case to trace the source of the infection, but it may have originated in the lungs, as both were found to contain tuberculous cavities as well as foci of bronchopneumonia.—*Norsk Magazine for Lægevidenskaben.*

Determining Causes of Genius.—Cesare Lombroso, writing on this subject, delivers himself as follows: "Sometimes surrounding influences, with predisposition and hereditary transmission, determine the form that genius shall take. So Darwin, St. Hilaire, Raphael, Bach, and Bernoullis were born of naturalists, painters, and mathematicians, and lived among them, finding in atavistic tendency and surrounding intellectual atmosphere the first cause of their later work. But this is not a general rule; on the contrary, geniuses, particularly the scientific, show a tendency to, I might say, dissimilar heredity, by means of which sons are as different as possible from their parents. Edgar Allan Poe was a descendant of rigid Puritans.

The Terminal Period of General Paralysis.—E. P. Chagnon concludes that general paralysis does not follow the regular cycle described by most authors. Nearly one-half of his patients died while still able to move about, and more than two-thirds never reached the period of absolute impotence. The marasmus described in the books is extremely rare, and eschars seldom occur. The ictus is rather a symptom than a complication of the disease; more than a third of the writer's paralytic patients died of ictus, and it frequently occurred in patients who died of intercurrent diseases.—*Bulletin Medical de Québec.*

MEDICAL RECORD:

New York, November 9, 1901.

SMALLPOX AND VACCINATION.

THE outbreak of smallpox on a somewhat large scale in London has, in the natural order of things, once again brought forth bitter denunciations of vaccination and its upholders. The antivaccinationists are, as usual, profuse in language and vehement but loose in argument, and endeavor to depreciate the value of Jenner's discovery by declaring that the decrease of smallpox is due to improved sanitation. That the disease should have diminished both in prevalence and severity since the introduction of vaccination they profess to regard merely as a coincidence. So much has been written upon the subject of vaccination that it would be a wearisome and unnecessary task to reiterate even some of the conclusions definitely arrived at with regard to its benefits.

The *London Saturday Review*, October 5, has an especially acute criticism of the attitude of the scoffers, and one or two opposite points are exceedingly well put.

The writer of the article remarks that the details of a complex problem, involving the delicate interplay of the activities of life, the attractions and repulsions of contending cells, the production and warfare of toxins and antitoxins, the nature of microbes and microbial poisons lie in a region closed and unprofitable to a layman. A special aptitude, a long training, and a constant and assiduous devotion are requisites of the modern bacteriologist, and it is only the bacteriologist who is in a position even to understand the evidence that has accumulated regarding the artificial reduction of relative or complete immunity to a disease. And this is the more so because the production of immunity by vaccination, for long and isolated empirical result, hit upon by what may be called a happy chance, and at its inception out of line with what was known of disease, has now, by the vast growth of knowledge, taken its place as one particular problem exactly congruous with the problems raised by study of the vast majority of diseases. Had Jenner not existed, were smallpox a new plague, suddenly brought to Europe from some remote part of the earth, modern bacteriologists, from their knowledge of other diseases, would be seeking for some means of producing immunity much on the lines of Jenner's empirical solution. The scientific discussion of vaccination, as a biological process, must be life to biologists, and in particular to those biologists who make pathological bacteriology their especial subject.

The truth undoubtedly is that the ordinary individual has not the trained intelligence necessary to understand more than the rudiments of the matter, and is consequently precluded from passing an opinion of any value. The opponents of vaccination are, for the most part, incapable, through their ignorance of bacteriological science, of judging of the merits or demerits of the method; but led away by their emotions, they play upon the feelings of the masses and create a prejudice against vaccination in the same way as they, or their like, have stirred up an adverse sentiment against every form of medical study and investigation.

THE GENESIS AND DEVELOPMENT OF PRIVATE HOSPITALS.

INSTITUTIONS of this nature are springing up with much rapidity in the large cities of the United States. Private hospitals, maisons de santé, private sanatoriums, surgical homes, nursing homes, have been known for a considerable period in the Old World, and in certain cities of Great Britain have flourished exceedingly. Hand in hand with the extraordinary advance of modern surgery, rendered possible by the introduction of asepsis, the creation and multiplication of private hospitals have occurred.

In Great Britain, where the conditions regulating hospital management differ widely from those which obtain in this country, the reasons for the innovation were, at any rate in the first instance, rational and easily comprehensible. Surgical interference, undertaken with close regard to antiseptic principles, had been shown to be attended with results which, when compared with those prevailing under the old system, seemed little short of miraculous, and robbed the knife of much of its terror. Persons of means were willing to pay for, and surgeons were eager to furnish, facilities for operating which would ensure the minimum of danger to life. Such advantages were not easily attainable in the wards of a general hospital. Pay patients were but a few years ago almost unknown in the British hospitals, and even now are the exception rather than the rule. Thus a wide and untrodden field was opened to the surgeon ambitious of demonstrating his skill, and incidentally gathering in fame and money.

At the present time, private hospitals, nursing homes, and similar institutions abound in London and in other large English cities, and the question now arises as to whether the field is not being somewhat overworked.

Here, however, where the pay system in hospitals is overwhelmingly in evidence, there would appear to be room for, and perhaps need of, private establishments for the treatment of disease and of injuries. Objections, some illusory, others founded on a sound basis, may be brought against public hospitals.

The benefits accruing to a patient provided by a private hospital, and lacking in a public institution, are many of them too obvious to require much verbal demonstration, the chief of which undoubtedly is that, with almost equal privacy and with all necessary home comforts, a treatment can be followed without that domestic chaos supervening which is unavoidable when a person's own house is used as the scene of medical or surgical service.

A strong tendency on the part of physicians of the large cities of the United States to establish private hospitals has been exhibited recently, and it will occasion no surprise among those who study the signs

of the times if this inclination in favor of institutions in which lay management has no part should spread. Practical experiments in this direction, upon an extended scale, will afford the experience required fully to test the point.

THE LIGHT TREATMENT OF SKIN DISEASE.

Some forms of skin affections have been shown within recent years to be remarkably amenable to treatment by means of light. Finsen of Copenhagen was the first to ascertain this fact, and to put it to successful practical proof. Such good results were obtained by his method, and by adaptations thereof, that dermatologists generally became convinced that the Danish physician had made a discovery of more than ordinary value, and that it behooved them to follow so promising a lead, and furthermore thoroughly to investigate the matter, with the view to improve upon the methods in vogue.

At the meeting of the British Medical Association, which took place during the past summer, no discussion evoked more enthusiasm than that in the section on dermatology, dealing with the light treatment of skin affections. Mr. Malcolm Morris, than whom there is no more earnest and strenuous worker in his chosen field, was the first to review the arguments for and against the light treatment from the standpoint of the dermatologist. Mr. Morris disclaimed any rabid partisanship in favor of the new methods, but at the same time stated his strong belief that under many circumstances no mode of treatment is better calculated to afford relief to those suffering from a certain class of skin disease than is the light treatment. The advantages of the method, according to his experience, were, he said, its reliability, its painlessness and its satisfactory cosmetic results. The reverse of the picture showed that the time required for treatment was long, and that the attendant expenses were exceedingly heavy.

The next to speak on the subject was Dr. Sequeira of the London Hospital, Whitechapel, whose remarks are worthy of close attention, because, in the first place, he is in charge of the largest installation of the light plant used for therapeutic purposes in Great Britain, where sixty or seventy patients are treated daily; and, in the second place, because to him belongs the credit of having discovered the exceedingly beneficial effects exerted by the *x*-rays upon rodent ulcer.

Finsen, when he began his light treatment, made use of the sun, but as it is by no means a constant visitor in Copenhagen, he was compelled to have recourse to electric light, and to this fact and to the cumbersome apparatus by which was utilized the light thus obtained, the almost prohibitive expense of the system has been due. Dr. Sequeira, however, has so far modified the objectionable arrangements that he has not only simplified the treatment by Finsen's method, but he has very materially reduced the cost. The outlook, therefore, for treatment conducted upon this plan is hopeful.

Since the *x*-rays have been found to be efficacious in treating some skin affections, a few injudicious supporters have somewhat lost their heads with regard to the matter, and have asserted that this form of light treatment must assuredly supersede every remedy for skin complaints as yet known, and that it is almost a panacea for all diseases. Dr. Norman Walker wisely threw a certain amount of cold water upon this ill-judged enthusiasm, and with canny Scotch caution gave as his opinion, at the Cheltenham meeting, that both the light methods of treatment were efficacious in combination with the older and more familiar methods. Rays are the most suitable treatment for extensive rodent ulcer; but in more limited cases of lupus, where the appearance has to be greatly considered, then the Finsen method, with its extremely perfect scar, is to be preferred.

Regarding the situation from an impartial point of view, and while acknowledging that the light treatment is but yet in its infancy and may accomplish all that its most ardent adherents now claim for it, the wisest course will probably be to refrain from a decided expression of opinion until both methods have been more thoroughly tested than has been at present the case.

THE EDUCATION OF CHILDREN.

Education of the young and the means to be employed successfully to attain this end have been for years past a fruitful theme for discussion among philanthropists. There are those who declare that the value of education—as it is known in these days—has been much overestimated, and provided that a youth possesses sufficient knowledge to make his way in the world, and enjoys good health, his equipment for the battle of life is satisfactory.

This view of the case is no doubt true so far as it goes, and it is undeniable that over-exerting the immature brain at the expense of the body is radically wrong; but, on the other hand, in almost all paths of life, the well-educated individual, given other conditions equal, has the advantage over the one whose mental powers have not been so efficiently trained. Education conducted upon rational lines—that is, paying due attention to the needs of the body while bringing out judiciously the intellectual capacities—is a boon of great value. It would seem, however, judging from the reports published in many of the New York lay journals, that the care of the young from an educational point of view is being greatly neglected in this city. The statement has recently been made that a very considerable number of children in the boroughs of Manhattan and The Bronx are unable to avail themselves of the advantages of education, owing to the fact that the school accommodation is inadequate.

This defect should be remedied as soon as possible, for it is a grave blot upon the fair fame of perhaps the richest city in the world, and the metropolis of certainly the wealthiest and most advanced country in that she should not afford facilities *for education* in keeping with her acknowledged elevated position.

American Courtesies to Professor Waldeyer.—Professor Heinrich von Waldeyer, President of the Academy of Sciences of Berlin, after a complimentary dinner given to him in New York, visited the Georgetown University, D. C., at which institution he was tendered a reception. In an address to the students he expressed his high appreciation of American medical education, and maintained that it was on a par with that of any part of Europe. Drs. Klober, Baker, and Joseph Taber Johnson acted as hosts of the occasion. Professor Waldeyer was also tendered a reception at the Cosmos Club.

News of the Week.

The Medical and Chirurgical Faculty of Maryland has begun a process of absorption of various special and local societies, the present members of the latter constituting themselves members of sections of the faculty. It is proposed to organize five sections of clinical medicine and pathology, surgery, obstetrics and gynecology, neurology and psychiatry, and ophthalmology and otology. The first of the separate societies to surrender its anatomy and become merged in the State society is the Clinical Society of Maryland, which voted to take this step at a meeting held on October 18.

Journal of the Association of Military Surgeons of the United States.—At the meeting of this association, held early in the summer at St. Paul, it was decided to publish the transactions hereafter in journal form, and the first issue of the same, dated August, has recently appeared. For the first year the journal will be published quarterly, but it is hoped to issue the numbers monthly thereafter. The expressed aim of the journal is to aid in the advance of military surgery, medicine, and hygiene, as well as to publish the transactions of the association. The fact that the editor is Dr. James E. Pilcher, Major and Surgeon, U. S. A., is in itself a guarantee of the success of the new undertaking.

An Impractical Suggestion in Higher Stirpiculture.—The Huxley lecturer before the British Anthropological Institute this year, Francis Galton, took as his theme the improvement of the human race by scientific selection. He advocated action by the state absolutely forbidding marriage to any but the healthy, and the morally and mentally superior. These favored ones should not be forced to grinding labor or any work that would cause physical deterioration, all this being done by the defectives whose mission was not to procreate. The difficulty would be to persuade the latter that it was their duty to work without hope of reward for their self-constituted superiors, and to prevent revolution.

Naval Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the Medical Corps of the Navy, week ending November 2, 1901: October 26—Assistant Surgeon R. T. Orvis, detached from the *Pensacola*, upon reporting of relief, and ordered home and to await orders. Assistant Surgeon U. R. Webb, ordered to the *Pensacola*, as relief of Assistant Surgeon R. T. Orvis. October 28—Medical Inspector F. Rogers, having been examined by a retiring board and found incapacitated for active service on account of disability incident thereto, is retired from active service, October 28, 1901, under the provisions of section 1453, Revised Statutes. Surgeon D. O. Lewis detached from the *Philadelphia*, ordered home and granted sick leave for three months. October 29—Passed Assistant Surgeon R. T. Orvis, commissioned Passed Assistant Surgeon from May 27, 1901. Passed Assistant Surgeon G. L. Angeny, commissioned Passed Assistant Surgeon from September 16, 1901.

Christ's Hospital, Jersey City, N. J.—The semi-annual dinner of the Alumni Association of the Internes of Christ's Hospital, Jersey City, was held at the Union League Club, Jersey City, on October 21. The following are the officers for the ensuing year: *President*, Dr. Henry Spence; *Vice-President*, Dr. John C. Parsons; *Secretary and Treasurer*, Dr. Wallace Pyle.

Philadelphia Polyclinic.—Dr. John H. Gibbon has been elected professor of surgery in succession to Dr. T. S. K. Morton, who had resigned, and was elected Emeritus Professor. Dr. Samuel McC. Hamill and Dr. James H. McKee have been elected professors of the diseases of children.

The Mental Condition of Czolgosz.—Drs. Fowler, Crego, and Putnam, the physicians who were requested by District Attorney Penney to examine into the mental condition of Leon F. Czolgosz, the assassin of the President, have made public their report, in which they say that he was sane. "The most careful questioning," the report states, "failed to discover any hallucination of sight or hearing. He had received no special command; he did not believe he had been especially chosen to do the deed. He always spoke as his motive for the crime as duty; he always referred to the anarchists' belief that the killing of rulers was a duty. He never claimed the idea of killing the President was original with him, but the method of accomplishing his purpose was his, and that he did it alone. He is not a case of paranoia, because he has not systematized delusions reverting to self, and because he is in exceptionally good condition and has an unbroken record of good health." The assassin was executed on October 29, and the autopsy was made by Drs. Edward A. Spitzka and Carlos F. Macdonald of New York, and Dr. John Gerin, prison physician. The autopsy occupied over three hours, and embraced a careful examination of all the bodily organs. The examination revealed them in a perfectly healthy state. All of the physicians who attended the execution were present at the autopsy, and all concurred in the findings of the examiners.

The Associated Physicians of Long Island.—The eleventh annual meeting of this society was held at Garden City on October 19, under the presidency of Dr. William B. Gibson of Huntington. The following officers were elected: *President*, Dr. William B. Gibson of Huntington; *Vice-Presidents*, Drs. Calvin F. Barber of Brooklyn, James S. Cooley of Glen Cove, and W. H. Ross of Brentwood; *Secretary*, Dr. James Cole Hancock of Brooklyn; *Treasurer*, Dr. John P. Heyen of Northport; *Board of Directors*, Drs. James M. Winfield, William B. Gibson, Calvin F. Barber, James Cole Hancock, and John P. Heyen.

The Montefiore Home.—The seventeenth annual meeting of the officers and directors of the Montefiore Home for Chronic Invalids was held last Sunday morning. The annual report was read showing that there are at present 236 patients in the home, and 113 in the sanitarium. The total number of patients treated during the year was 737. Of this number 151 died. There were 1,095 applications for admission, 423 being admitted, and of this number 34 are still awaiting room. The per capita annual support for each inmate amounted to $255.23.

Accusations Against a Trained Nurse.—A woman named Jane Toppan, a trained nurse, was arrested on October 30 in Amherst, N. H., on suspicion of having caused the death of a woman whom she had been nursing. Since her arrest, inquiry has developed the fact that twelve persons have died while she was in attendance as nurse, ten of these deaths having occurred within the past two years.

Alleged Maltreatment of the Insane.—Another insane patient has died at Bellevue, whose body after death was found covered with bruises. The man was very violent when admitted, and was said to have constantly beaten himself with all his force until bound with a restraining belt. In the Asylum for the Insane at Dunning, Ill., two female nurses have been charged with having caused the death of two female patients in the asylum by deliberately withholding food from the patients, sometimes giving them nothing at all, and for weeks nothing but bread

and tea. It has also been charged that medicine provided for the patients were not administered to them. The motive assigned in the charges is that the patients were especially obnoxious to the nurses, and that their course was prompted by a desire to so weaken the patients that they would become ill and be sent to a ward for the sick, thus relieving the nurses of the care of them.

Tetanus Attributed to Infected Diphtheria Antitoxin.—Nineteen cases of tetanus have been reported in St. Louis among children who had received injections of anti-diphtheritic serum. The antitoxin used in these cases was prepared by the City Board of Health. Inoculation of guinea-pigs with the suspected antitoxin has been followed by symptoms of tetanus. The horse from which the serum was obtained on several occasions, the last time on August 24, developed symptoms of tetanus on October 1, and was killed.

Army Emergency Rations.—In the annual report of the Commissary General of the Army, made public the first of this month, is an account of a number of practical tests of the value of certain emergency rations. A board was appointed to try each ration on soldiers in actual field service, the precaution being taken to march the men into an uninhabited region of the Indian Territory, so that they could not obtain food surreptitiously should the emergency ration fail to satisfy hunger. Of all the rations tried, the only one that gave satisfactory results was one prepared by the board which consisted of cakes of chocolate and of compressed meat and bread.

Accused of Smuggling Surgical Instruments.—A customs inspector a few days ago seized surgical instruments to the value of $1,500, alleged to have been smuggled by a Wisconsin physician who had just returned from Germany.

A Dinner to Dr. Thomas.—A dinner will be given on November 21 to Dr. T. Gaillard Thomas of this city in celebration of his seventieth birthday. The medical friends of Dr. Thomas who wish to honor him in this way are requested to communicate with Dr. A. J. McCosh, 16 East Fifty-fourth Street.

The Prevention of Typhoid Fever in Germany.—Typhoid fever is reported epidemic in several towns in Prussia, 1,329 cases having been officially reported in one town (Bochum). In consequence of this, unique precautions to prevent the spread of typhoid have been inaugurated on the Prussian State railways. A dispatch to the *Herald* says that practically every station will be turned into a quarantine depot and every station master into a health officer. In addition to being ordered to maintain scrupulous cleanliness throughout the station premises, station masters have been instructed to furnish to a physician accompanying every through train a detailed report of any typhoid cases in his town or any symptoms thereof. If fever conditions are found to exist, the station master must furnish freshly boiled water for the use of passengers and crew, as well as maintain tanks of sterilized water conspicuously designated for use of the traveling public. The regular stationary drinking fountains must be sealed up until the town is fever free. The medical authorities who framed the new regulations assert that railway travelers and railway coaches are among the most prolific carriers of contagion.

King Edward's Health. The discussion over the King's health has extended to the medical journals. The *Medical Press and Circular* of October 31 prints the report that papillomatous growths have on three occasions been removed from the King's left vocal cord, and that an immediate operation of another nature has since been rendered necessary, and calls for an official announcement as to the truth or falsity of these rumors. The *Lancet* of November 2 says: "There is every ground for believing that the rumors in regard to the King's health are entirely untrue. His health is good, and he has undergone no operation whatever." The *British Medical Journal* of the same date also says that the King's health is good, and that no operation has been performed on him. A dispatch to the *Sun* says that it is known that his Majesty's throat has been subjected to spray treatment for several months. The King himself traced the trouble, which first made itself known by the appearance of blood, to his throat. Knowing the royal family's predisposition to cancer, he was naturally alarmed, and specialists were called in. They diagnosed the trouble as smoker's throat, and prescribed complete abstinence from tobacco. The King has always been a very heavy smoker of cigars and cigarettes, and when he demurred to such drastic treatment, his advisers compromised the matter by greatly reducing his daily allowance of cigars and cutting off cigarettes altogether. Denials of the cancer story also come from Professor Ehrlich of the Bacteriological Institute of Frankfort, to whom it is said some tissue was submitted for examination, and from the *Official Gazette* of Copenhagen. This journal declares untrue the report that specialists were in consultation regarding him during his recent visit to Denmark.

A Nothnagel "Festnummer."—The issue of the *Wiener klinische Rundschau* for October 9 is dedicated to Professor Nothnagel in honor of his sixtieth birthday, which occurred on September 28. There are twenty-six original communications in the number, contributed by friends and admirers of the great clinician, and an artistic reproduction of a recently painted portrait is the frontispiece.

The Importation of Vaccine Needles.—A novel case was recently decided by the U. S. General Appraisers. A company dealing in antitoxins and vaccines recently protested against the action of the Chicago Collector of Customs upon an importation of cambric needles charged with anthrax vaccine, in admitting the vaccine free, but subjecting the needles to a duty of 25 per cent. ad valorem as "needles not specially provided for." The importers set up that either the needles were hand-sewing needles, and that they were properly entitled to free entry, or that the virus and needles were entireties and were entitled to free entry as virus. The claim that the virus and needles are entireties is not sustained, but it is decided that the needles, being hand-sewing needles, must be so classified, and that they come in free, being specifically provided for.

Dr. Bulkley's Lectures on Skin Diseases.—The governors of the New York Skin and Cancer Hospital announce that Dr. L. Duncan Bulkley will give a fourth series of clinical lectures on diseases of the skin in the out-patient hall of the hospital on Wednesday afternoons at 4:15 o'clock. The series began on November 6. The course is free to physicians.

The Consumption of Alcohol in Germany.—A dispatch to the New York *Times* states that at a meeting of the Society for Combating the Abuse of Spirituous Liquors, held recently in Breslau, one of the speakers, Baron von Diergardt, said that he believed alcohol would one day be universally regarded as an enemy of civilization, but at present it was only possible to recommend moderation in its use. Seven hundred and fifty millions of dollars was yearly spent in Germany on intoxicating liquors.

It was estimated that the average German consumed the equivalent of five glasses of spirits a day. Baron von Diergardt added that one difficulty in the campaign was that the State itself was interested in alcohol, deriving, as it did, a revenue of $41,000,000 from spirits and $25,000,000 from beer. One-third of the German exports to Togoland and one-seventh of those to East Africa consisted of alcohol.

Philadelphia County Medical Society.—At a stated meeting held October 23, Dr. Wilmer Krusen read a paper entitled "Triple Ectopic Gestation, with Report of a Case." Dr. Andrew J. Downes presented a communication entitled "Some Pertinent Remarks on Appendicitis in the Female." Dr. Joseph Sailer made a report upon "Two Cases of Diphtheritic Infection of the Mouth, Following Typhoid Fever." The patients were members of the same family, and in both a condition of noma developed. In one, diphtheria had been present more than a year previously. Typhoid fever occurred also in a third member of the family. Dr. John H. W. Rhein read a paper entitled "The Treatment of Locomotor Ataxia, with Special Reference to the Treatment by Educational Exercises." The latter are directed to a training of muscular and remaining nervous structures, and if faithfully practised are capable of bringing about most marked improvement in co-ordination. The mental state also is often happily influenced.

Philadelphia Neurological Society.—At a stated meeting held October 22, Drs. F. X. Dercum and W. W. Keen presented "Two Tumors of the Frontal Lobe." Drs. Max H. Bochroch and Alfred Gordon read a paper entitled "A Case of Multiple Lesions of the Spinal Cord and Cranial Nerves, with Amyotrophy, Probably Due to Syphilitic Infection." Dr. William Pickett read a paper entitled "Paresis: A Study of 149 Cases Occurring at the Philadelphia Hospital." Dr. John K. Mitchell described "An Unusual Symptom in a Case of Insanity." The patient, a man of intelligence, displayed an imperative impulse to arrange objects in groups of three, and in reading to mutilate, by tearing or cutting with a knife, pages on which the figure or the word three or multiples thereof occurred. Dr. Joseph Sailer read a paper on "The Supraorbital Reflex." He referred to three cases of facial palsy in which this reflex, which consists in contraction of the levator palpebræ when the brow is struck, was wanting. Dr. D. J. McCarthy, who was the first to describe the phenomenon, cited evidence to show that it was a true reflex, the arc including the trifacial and facial nerves. It may be a means of differentiating supranuclear from infranuclear facial palsy.

Pathological Society of Philadelphia.—At a stated meeting held October 24, Dr. R. C. Rosenberger read a paper entitled "Comparative Experiments with Neutral Red Agar and Neutral Red Bouillon." Dr. J. A. Scott presented a specimen of "Amœbic Abscess of the Liver." The collection of pus occupied the right lobe of the liver and had ruptured successively into the right pleura and the bronchi of the right lung. Aspiration during life resulted in the evacuation of considerable amounts of fluid. There was no increase in the number of leukocytes until a short time before death. Dr. Scott presented also a heart with marked mitral obstruction, less marked bicuspid obstruction and atheroma of the pulmonary artery. The left ventricle was small and its walls thin, and the right ventricle large and its walls comparatively thick. The left auricle was greatly dilated and it contained two ante-mortem clots. The right pleural cavity contained considerable fluid, and the liver, which was [illegible] diminished in size, was displaced downward, so that during life this organ was thought to be enlarged. The kidneys contained old infarcts.

Drs. Chas. W. Burr and D. J. McCarthy exhibited "A Brain with Internal Hydrocephalus." The patient had been a man with a large head of good shape and of the average intelligence of his class. He had had two or three attacks of insanity. The lateral ventricles were greatly distended.

Dr. Jos. Sailer exhibited sections of skin from a case of undetermined character. The patient was a colored child, eight years of age, who presented a lesion of the face suggestive of ringworm. The growth progressed from the periphery, leaving a central area covered by smooth, thin skin. Clinically a diagnosis of syphilis had been made, but leprosy or some form of tuberculosis or blastomycetic dermatitis was taken into consideration. Histologically giant-cells were visible, but no bacteria of any kind had been found.

An Association of the French-Speaking Physicians in North America is to be organized in Quebec in 1902 during the semi-centennial celebration of the foundation of Laval University. Members of the association need not be of French or French-Canadian birth, but they must be able to speak French, as all the scientific and other work of the society will be conducted in that language.

The New York State Association of Railway Surgeons.—The eleventh annual meeting of this association will be held at the Academy of Medicine in this city on November 14 and 15, under the presidency of Dr. W. R. Townsend of New York. The secretary of the society is Dr. C. B. Herrick of Troy. The subject for the set discussion at the opening session will be railway sanitation. The program contains the names of many men from other States who will read papers or take part in the discussion.

Obituary Notes.—Dr. William M. Hudson died at his home in Hartford, Conn., on October 30, at the age of sixty-eight years. His death was the result of a cold contracted during his attendance at the Yale bicentennial celebration. He was a graduate in arts of Yale in 1854, and in medicine of the now extinct Pennsylvania Medical College of Philadelphia.

Dr. J. Mortimer Crawe, Sr., one of the oldest practising physicians of Watertown, N. Y., died October 29, aged seventy-one years. He was a graduate of the Jefferson Medical College in 1850, and was a member of the New York State Medical Association and of the Jefferson County and Watertown City Medical societies.

Dr. Faure Miller, a well-known physician and a prominent member of the Anglo-American Continental Medical Society, died in Paris on November 4, aged sixty years.

Dr. Genit D. Van Vranken died at his home in Hempstead, Long Island, on November 1. He was born in Clifton Park, Saratoga County, N. Y., July 2, 1841. He was graduated from the Jonesville (N. Y.) Academy and entered Union College, from which he was graduated in the class of 1863. For several years afterward he was professor of sciences in the Jonesville Academy, but finally decided on medicine as a profession. He attended the Albany Medical School and later the Philadelphia School of Medicine. He practised medicine for some years at Jonesville, but gave up general practice to accept the place of house physician in a sanatorium in Saratoga. He retired from practice many years ago.

Correspondence.

OUR LONDON LETTER

[From Our Special Correspondent.]

SCHOOL OF TROPICAL MEDICINE—THE SOCIETIES—CANDIDATES FOR COUNCIL—GUILD OF ST. LUKE—SMALLPOX—THE LATE MR. VINCENT JACKSON.

London, Oct. 5, 1901.

The London School of Tropical Medicine is making determined efforts to keep itself before the public. It may be there is a little rivalry with Liverpool, and a resolve to justify its existence, the necessity for which you know was at first disputed. On Wednesday afternoon the third session was opened by Lord Brassey, who said more funds are required, and boldly asked for £100,000. He did not consider this a large sum for such an institution, and said a favorable response must come from the large section of the public interested in the tropics. Dr. Manson followed, and said, at the outset, medical men proclaimed from platform and press that the schools could supply all that was required. Such opinions he regarded as "vamped-up figments of the imagination," and with questionable taste went on to talk of "errors in diagnosis made by ships' doctors and others," illustrating them by a case of a negro admitted to the Seamen's Hospital with a tropical disease of which the medical men who had previously seen him knew nothing. Sir Francis Lovell then spoke of a visit he will make to India, Burma, Ceylon, the Straits Settlements, China, Japan, New Zealand, Australia, America, and Canada in the interests of the school—a tour of the world to inform wealthy residents of the need of further funds.

After the meeting, Dr. Manson gave an interview to the press, the use of which is not very apparent. He made one statement, however, which is worth repeating, viz., that in conversation with Professor Koch he found out that Germany spent five times as much as England on the study of tropical diseases. Englishmen go out for study and research for a mere pittance. Germany pays her men a comparatively handsome salary.

The societies are now in full work. At the Pathological, as usual, there were important points brought forward, and specimens shown.

The Clinical Society began the session on Friday last with interesting surgical cases. Quite a rarity was one of displaced strangulated femoral hernia, told by Mr. Bryant. The case was of importance to every practitioner, as it showed the danger of forcible attempts to reduce by the taxis, and the difficulty of diagnosis that may arise when there is no history. In fact, but for the distinct history of an old femoral hernia there was not sufficient indication in this case that the obstruction of the bowels was due to such a hernia being strangulated. Apart from the history, abdominal section might thus have seemed indicated, but if undertaken would have been useless, for the seat of strangulation was outside the abdominal cavity. An exploratory operation in the femoral region was determined upon in accordance with the good old rule of first examining, in every case of obstruction associated with hernia, the region in which the hernia existed. Mr. Bryant operated in the usual manner. The crural sheath, which on exposure did not seem expanded, was opened with great care, and a small piece of tissue looking like omentum found, but no bowel; the femoral ring was clear, and on passing a director, a piece of pale intestine, which had been collapsed and not seen, became suddenly distended, and was lost downward through a narrow opening at the apex of the femoral sheath, where it was strongly held and strangulated. This constriction was divided on a director, and four or five inches of highly congested intestine drawn out and returned to the abdomen. Though the operation was thus completed, the patient sank, and the post mortem examination showed that the hernia had been forced through a rupture of the femoral sheath at its lowest part or apex into the connective tissue of the thigh on the inner side of Scarpa's triangle, and that the seat of strangulation was not at the ring, but at the seat of the rupture of the sheath. The specimen is now in the College of Surgeons' Museum. The patient had been troubled with the hernia for about five years, but had not worn a truss. She had usually reduced it herself, and had sometimes used considerable force, and no doubt on the last occasion had caused the displacement, as symptoms set in two days afterward.

The president (Mr. Barker) presented an exactly similar case. He had himself abandoned the taxis, and questioned if it ever should be tried, and thought if this view were endorsed by Mr. Bryant, it would have a good effect both in private and hospital practice. Mr Golding Bird endorsed this view, and Mr. Bryant agreed so far as femoral hernia was concerned. Inguinal was rather different, but in that anything like violence was injurious. In scrotal hernia, too, there was less danger than in femoral.

At the same meeting, Mr Jackson Clarke read notes of a case of painful backward projection of the tips of both twelfth ribs succeeding kyphosis in a nurse-maid. When the spinal support was discontinued, the pressure of even her dress on the ribs was painful. As much of each twelfth rib as could be taken away without incising the erector spinæ was removed, nearly one inch. Mr. Clarke regarded the case as rheumatoid. Dr. Ewart said a condition called acrochondralgia was known as a localized ailment due to various causes aggravated by the pressure of corsets. He was surprised to hear of osteoarthritis being relieved by excising a bit of distal bone, and would like to have further evidence of that disease.

Mr. Cuthbert Wallace read notes of cases of injuries to joints—some wounded by compound fractures, others of probable or doubtful nature, as in the case of punctured wounds which might have penetrated. He thought, with a large external wound and only a small one entering the joint, it was worth while to give the joint a chance. Cleansing, he said, must be mechanical: it was no good trusting to antiseptics. The President said antiseptics were useless, and often worse. For many years he had only employed irrigations with normal saline solution, since which his results improved. He laid it down as a principle that, once a joint became infected, it could not be disinfected.

Mr. Wallis referred to some similar cases he brought before the society in 1898. If perforating wounds of joints became at all inflamed, he found a free opening and drainage gave good results.

Mr. Mansell Moullin then read notes of five cases of ascites dependent upon cirrhosis of the liver, in which he had sutured the omentum to the anterior abdominal wall, with a view to establishing a collateral circulation after the Drummond-Morison method. Two of the five cases died, the operation being too late; one could not be traced; the other two are alive and at work now, two years after the operation. Mr. Moullin did not consider the risk of the operation serious. The mortality, he admitted, had at present been high, but that was the case with all new operations, and would fall with more careful selection.

At the Obstetrical Society, Dr. Herman reported a case of leukæmia in pregnancy, and remarked on twelve others published elsewhere. Examining them critically, he found the evidence of leukæmia deficient in five, so that there were only eight cases from which to draw conclusions. He advised the induction of abortion or premature labor as the treatment of these cases—not in all indiscriminately, but only in those in which the symptoms caused suffering and were aggravated after the onset of pregnancy.

At the Gynæcological Society, on the 10th inst., Dr. Macnaughton-Jones read notes of a series of cases, and Dr. W. Travers gave an account of a case of fibroid tumor causing obstruction of the bowels and simulating appendicitis.

Candidates for the General Medical Council are beginning to move. Mr. Victor Horsley's intention to resign in order to have a single election is to be defeated. The draughtsman of the act has made him ineligible for re-election—evidently contrary to the intention of Parliament.

Members of the Guild of St. Luke have again disported themselves in academical college robes at St. Paul's Cathedral.

The epidemic of smallpox has continued at about the same rate. The school board has continued its obstruction at the bidding of some members who pander to the anti-vaxs.

Mr. Vincent Jackson, J. P., Surgeon to the Wolverhampton Hospital, died on the 12th inst., aged sixty-seven. He was a notable surgeon, and his opinion much valued by his brethren. He was energetic, too, and spent some of his energy in public life, was elected an alderman, and made a magistrate. He was interested in the well-being of the profession, a reformer in many ways, and one always worth listening to. He was a rather voluminous writer on various surgical subjects, *i. e.* stricture, the knee-joint, lithotomy, colotomy. His last work was an "Historical Sketch of the Medical Profession or Medical Education in Great Britain."

The Tri-State Medical Association of Mississippi, Arkansas, and Tennessee, will meet in Memphis, Tenn., on November 19, 20 and 21. The president is I. A. McSwain, M.D., of Paris, Tenn., and the secretary Richmond McKinney, M.D., of Memphis. Many interesting papers are promised and a large attendance is expected.

LETTER FROM NEW ZEALAND.

(From Our Special Correspondent.)

GRIEF FOR PRESIDENT MCKINLEY—INFLUENZA—ALEXANDER'S OPERATION—LAW AGAINST OPIUM SMOKING—PROHIBITION OF THE SALE OF PREVENTIVES OF CONCEPTION.

AUCKLAND, N. Z., September 20, 1901.

I AM writing this on the day of President McKinley's funeral, and it is impossible to write at all without commenting on his death, and on the way in which the news has been received here. Are we becoming more emotional, or, if not, what becomes of the stolid, unexcitable Anglo-Saxon in this Southern hemisphere? Ever since the news of the dastardly and atrocious attack on your President reached here, there has been one and almost only one topic of conversation. During last week intense anxiety gave way for a time to hope, and then for most of us, almost to a certainty, of recovery. I have seen too much of gunshot wounds to be so confident as the President's surgeons apparently were, and had expressed to your Consul, Mr. Dillingham, when I first called on him, my doubts and fears. When the disastrous news came on Saturday evening that the President was sinking, you would really have thought that every one you spoke to was losing a near and dear relative. The emotion exhibited was extraordinary. Old men and men of the world spoke in husky tones, with the tear forming, and very near falling. On the Monday, when the news came of the death, on the King's ship in the harbor the American flag was hoisted half-mast high, and every one who had a flag and a flag-staff hoisted either the Stars and Stripes or their own national flag half-mast with a strip of black.

Now, I can well remember when the news of Abraham Lincoln's assassination reached England, and although there was a universal feeling of indignation and horror at the crime, there was no such manifestation of general mourning as we have made here. Is it that the effect of rapid locomotion, of telegraphs, and telephones, and the constant influx of news from all parts of the world, have combined to make the generation brought up under their influences more sensitive and more emotional?

Whatever may be the causes, I think any citizen of the United States who walked down our principal business street to-day, and saw on every public building, on every bank, on every large merchant's office or store the flag at half-mast, just as they were for our own Queen, must have been deeply gratified, and felt that, as one of your naval officers said, "Blood is thicker than water after all."

There was an article in a late number of the MEDICAL RECORD on the subject of influenza in Chicago, and its persistency in greater or less degree for the last ten years. Precisely the same phenomenon has occurred here. We have never been entirely free from it since it first appeared, I suppose about ten years ago, and this winter it has been very severe all over the Colony, but especially in Auckland. It leaves behind it an extraordinary amount of nervous depression which never entirely disappears unless the patient can get a change of air for a time.

It is interesting to medical agnostics like your correspondent, who has seen too many pathological theories brought forward as infallibly true, and too many methods of treatment vaunted as successful, to believe in any, to notice the perfectly cock-sure way in which the speakers at medical congresses express the most absolutely opposite opinions. We have had a striking example here recently in a discussion at the New Zealand Medical Association in Alexander's operation. Some condemned it as useless, others as impracticable, or at least extremely difficult, others strongly advocated it as perfectly safe, and thoroughly efficacious. Probably some of the last gentlemen have never heard their former patients of two or three years previously express themselves as to the results of the operation. If I might judge from what is going on here, I should venture to prophesy that the day of the operating gynecologist will soon be over. The everlasting operations on the uterus and its appendages, which have been the fashion of late years, are beginning to disgust the women themselves. At first, they were quite proud of these operations—a woman hardly felt herself in the fashion unless she had been curetted once or twice, or had an Alexander. Then came the rage for scooping out ovaries and uterus altogether, and spaying the women. Even this has become so common that it is no longer a distinction, and, besides, the women are not cured of their aches and pains.

Two stupid bills have been brought into our legislature, which has taken to meddling with everything. One is to try to abolish opium smoking of the Chinese. For this object the bill prohibits the importation of opium in any form in which it can be smoked—that is, it will prevent the importation of the crude drug, the gum and the powder. It also allows any policeman to make a raid at any time on any Chinese house, where he may suspect that opium smoking is being practised. Why on earth we are to trouble the Chinese for such a perfectly harmless vice (to others as opium smoking, nobody can say. In my opinion, it is done simply to annoy the Chinese, and give an opportunity to the police for blackmailing.

The other is the offspring of our Premier's horror at the decline of the birth rate. I have seen only the newspaper account of it, but it appears to be an act for preventing the sale or importation of rubber prunes. How the government will prevent the importation of rubber syringes and sponges is not quite apparent. The way in which we are being legislated for in these democratic colonies is perfectly ridiculous. I have lived under martial law in Russia, Cuba, and Venezuela, and under the mild but despotism of the Sultan in Turkey, but nowhere was my personal liberty so interfered with as in this British colony. We have the female franchise here!

EXECUTION AND AUTOPSY OF CZOLGOSZ

TO THE EDITOR OF THE MEDICAL RECORD.

SIR,—Agreeably to your request, the following brief account of the execution and autopsy of Czolgosz, the assassin of President McKinley, is respectfully submitted.

The execution by electricity of Leon F. Czolgosz, which took place in the State Prison at Auburn, N. Y., on the morning of October 29, 1901, terminated the earthly existence of the most monstrous magnicide of the age. Every precaution was taken by the Warden of the Prison, under whose immediate supervision and direction the execution was conducted, to minimize the opportunity for notoriety, as well as to insure that the taking off of the prisoner should be effected in an orderly and dignified manner.

The official witnesses, consisting of prominent New York State officials, several physicians, representatives of the respective press associations, and two official physicians—Dr. John Gerin, Prison Physician, and myself—having been assembled in the execution room and received the usual admonition from the Warden as to the maintenance of order and quiet during the execution, the prisoner was conducted to the room by a guard on either side a few minutes after 7 A.M. As he entered the room, his head was erect and his manner self-possessed and defiant. Immediately after being placed in the fatal chair, the binding straps were quickly adjusted to his arms, legs, and body; the head and leg electrodes were placed in situ and connected with the wire which was to transmit the lethal current through his body. The criminal offered no resistance whatever, but during the preparations addressed himself to the witnesses in the following significant language: "I killed the President because he was the enemy of the good people—the good working people. I am not sorry for my crime. I am sorry I could not see my father." At this juncture, everything being in readiness, the Warden gave the signal to the official electrician in charge of the switch, who immediately turned the lever which closed the circuit and shot the deadly current through the criminal's body. The instant the contact was made, the body was thrown into a state of extreme rigidity every fiber of the entire muscular system being in a marked condition of tonic spasm. At the same time, consciousness, sensation, and motion were apparently absolutely abolished.

Czolgosz was pronounced dead by the attending physicians and several of the other physicians present in four minutes from the time he entered the execution room, one minute of which period was occupied in the preliminary preparations, one minute and five seconds in the electrical contacts, and the remainder of the time in examinations by the physicians to determine the fact of death.

Two electrical contacts were made occupying in all one minute and five seconds. In the first contact the electromotive pressure was maintained at 1,800 volts for 7 seconds, then reduced to 300 volts for 45 seconds, increased to 1,800 volts for 4 seconds, and again reduced to 300 volts for 26 seconds, when it was broken. The second contact was maintained at 1,800 volts for 15 seconds. That conscious life was absolutely destroyed the instant the first contact was made, was conceded by all of the witnesses.

Immediately after the execution, the lay witnesses having departed, an autopsy was made by Mr. Edward A. Spitzka of New York, under the direction and supervision of the official physicians and in the presence of several of the visiting physicians who were invited to attend. The autopsy occupied more than three hours and embraced a careful examination of all the bodily organs including the brain, all of which were found to be in a perfectly

mental state [illegible] it was incurred in [illegible] the physicians present.

In compliance with the expressed wish of the relatives of the criminal, the Superintendent of State Prisons, who was present, and the Warden declined positively to allow any portion of the body to be removed from the prison. Consequently, and regrettably, it was impossible to retain honorable possession of any portion of the brain for future examination and study. Accurate drawings, however, and detailed anatomical descriptions of the brain were made by Mr. Spitzka for subsequent study and report. A careful, naked-eye examination of the brain in all of its parts was also made, and full notes taken thereof. The organ and its appendages appeared to be absolutely healthy and free from any abnormality whatever, thus corroborating the opinion of the mental experts who had examined the criminal during life—namely, that he was perfectly sane.

Respecting the question of Czolgosz's mental condition, it appears that all of the mental experts at his trial, on either side, namely, Doctors Putnam, Fowler, and Crego for the people, and Arthur W. Hurd and myself for the defence, after repeated examinations, concurred in the opinion that he was sane. A final examination of the criminal, with reference to his mental condition, was made by Dr. Gerin and myself at the Auburn Prison on the evening before his execution with entirely negative result. In fact, none of these examinations disclosed, in the opinion of any of the experts, the slightest evidence of mental disease or mental degeneracy. On the contrary, he was regarded as exceptionally intelligent for one in his walk of life. Furthermore, this conclusion was fully corroborated by his manner, appearance, and declarations in the execution room as well as by the post-mortem findings. Moreover, Czolgosz's bearing, conduct, and declarations from the time he murdered the President down to that of his execution have been entirely consistent with the teachings and the creed of Anarchism, and stamp him as an Anarchist of the deepest dye.

Progress of Medical Science.

The Boston Medical and Surgical Journal, October 31, 1901.

Association of Anæmia with Chronic Enlargement of the Spleen.—Arthur H. Wentworth concludes that the blood changes in so-called anæmia splenica are those of a secondary anæmia. The degree of cachexia does not always correspond to the blood changes, and may be due to toxic influences, although it is difficult to see how fibrous changes in the spleen can produce toxin. The statement is not warranted that this condition is related in any way to pseudoleukæmia. In the case of splenic anæmia, nothing characteristic of a primary disease has been discovered in any organ or in the blood. The evidence is conclusive that anæmia infantum pseudoleukæmica is a secondary anæmia, owing its symptoms and blood changes to the occurrence of severe anæmia at an early age. There is no apparent connection between the character of the blood and the splenic changes in infancy.

A Case of Anomia and Paraphasia. George H. Thomas reports the case of a man of sixty years, previously in excellent health and of retired habits, who suddenly began to have headaches, and to use profane language toward his wife. Difficulty of speech and forgetfulness were the next symptoms. Paraphasia and anomia became marked; there was no motor aphasia, no agraphia, no physical word-blindness, nor deafness. There was a purulent discharge from the left ear, and tenderness on pressure about three inches above the tip of the mastoid. Operation failed to discover any abscess, partly because the patient's condition was so poor that careful research was not possible. At the autopsy, an abscess cavity about the size of a walnut was found in the posterior part of the left lower temporal convolution, and was filled with thick, fetid-smelling pus of a gelatinous consistency. The surrounding tissues to a distance of about three fourths of an inch were softened.

Intermittent Hydrops. E. G. Brackett describes two cases of this affection, which is characterized by regular periods recurring of a constant length of duration and of intervals between the attacks and with no permanent resulting disability. Sixty-eight cases are on record. The joint most frequently affected is the knee, but hip, shoulder, elbow, wrist, ankle, jaw, and spine have all been attacked in various cases. The onset is sudden. As a rule, the disability is only that due to the mechanical hindrance of the effusion. Pain is very frequently absent, but in some cases is marked. Subjective languor is common during and after the attack. The duration varies, but is apt to be three or four days. The interval between attacks is curiously constant in each case for long periods of time. The usual period is fourteen days from the beginning of one attack to that of the next. The disease seems to be functional. It is hard to formulate treatment from the data on hand, but it seems fair to infer that quinine and arsenic and electricity should be tried. If this plan is unsuccessful, after an interval to allow for spontaneous remission, puncture and injections or open drainage may be resorted to.

Journal of the American Medical Association, Nov. 2, 1901.

Fat Necrosis from a Surgical Standpoint.—Carl Beck reports the case of a woman of twenty-six years, who suffered at intervals from attacks of biliary colic. Operation having been decided upon, the abdomen was opened in the median line. The omentum and the peritoneum of the intestines and mesentery were found studded with areas of white spots, from the size of a pinhead to 5 mm. in diameter. They were angular, flat, and somewhat depressed. Excision of a portion of omentum showed that they were areas of fat necrosis. The patient made a good recovery. The principal points in treatment, the author holds, are that no obstruction is left in the gall ducts before closing the abdomen. If we regard the obstruction of the common duct as the cause of fat necrosis, we must remove the obstruction at once, and not be satisfied with simply draining the gall-bladder, or the fat necrosis will progress and kill the patient.

The Treatment of Typhoid Fever in Children.—H. E. Tuley sums up his ideas in the following advice: Feed carefully, medicate cautiously, nurse vigilantly, bathe frequently, and give plenty of water internally. In feeding, the proteid element of food is to be cut down, even in children as old as ten years. This can be done by any one of the many methods of modifying milk. A child of five years does not need more than twenty to thirty ounces of milk in the twenty-four hours. A quart of water should be taken in the course of the period named, and if the child will not swallow that amount, some can be given by a saline enema. Fever may be reduced by sponging, tubbing, packs, or cold colon irrigations. Warm or tepid sponging will often act better than any form of cold bath. For diarrhœa, Tuley prefers bismuth and tannalbin. Strychnine is the remedy *par excellence* for a flagging heart. Whiskey should be reserved until late, and when given it should be with regularity and in a considerable dose.

A Report of Four Cases of Fat Necrosis in connection with Gallstones.—W. A. Evans believes that more attention should be paid to the differentiation of gallstones with necrosis from gallstones without it, though the point bears mainly just on the question of prognosis. Not much reliance can be placed on differences in fever, pain, or extravasated fluid in the two conditions. Patients with fat necrosis are apt to be restless, moving about, having a sense of something impending, and asked to be relieved of a something which they do not themselves understand and cannot clearly locate; when the patient is simultaneously suffering from gallstone colic, the sharp cutting pains, and the profound shock of the latter condition would completely mask the mild sensations of the first condition. In making a diagnosis of fat necrosis, we must bear in mind the possibility of gallstones with suppuration of the cyst and acute intestinal obstruction. In fat necrosis the pain is generally located in other regions than the gall-bladder. It is shifting and never very definitely located by the patient. In fat necrosis the pulse is generally more rapid. Moreover, there is a duskiness of the skin that we do not get in gallstones. Halsted and Opie have called attention to a passive congestion or deficient oxydation in the epigastrium in cases of fat necrosis, and this symptom calls, in the judgment of Evans, for further investigation.

New York Medical Journal, November 2, 1901.

Scientific Aids to Diagnosis.—Henry Holton makes a plea for the more general use of the ophthalmoscope by the general practitioner; also, for the systematic examination of the blood, careful examination of the urine, and the employment of the serum test in suitable cases.

Social Aspects of Dermatology. Malcolm Morris speaks in the eighth Lane Lecture of Neuroses of the Skin, which he divides into motor and sensory neuroses, angioneuroses, and trophoneuroses. Special attention is paid to the various forms of urticaria. This condition may occur mechanically from pressure of lymph on the blood vessels. The affection is often associated with functional and organic disease of the uterus and other organs, with nervous disorder, with gout, indigestion, jaundice,

rheumatism, and asthma. In the last case, the asthmatic symptoms are probably due to urticaria of the bronchial tubes. It is also often produced by external irritants, such as nettle stings, insect bites, the contact of hairy caterpillars, etc., and internal irritants, such as shell-fish, and in certain individuals, strawberries, parsley, oatmeal, etc. The neurotic temperament is a powerful predisposing factor, and a violent mental emotion may determine an attack.

American Medicine, November 2, 1901.

The Influence of Mental Depression on the Development of Malignant Disease.—Joseph D. Bryant, after careful study of statistics, states that it is not probable that mental depression exercises any influence in the causation of cancer, except through the blood impoverishment which almost invariably exists in melancholia (Steele), a change which appears not materially to influence the outcome in the man, as the percentage of affliction is substantially alike in this sex in all forms of insanity. Hence, it appears that the preponderance of malignant manifestations in woman should be attributed rather to the broader field of attack than to any form of special vulnerability.

Report of a Case of Poisoning from Nutmegs (Myristica Fragrans).—F. D. Merritt reports this case. The patient was a woman of twenty-seven years. She had suffered from menorrhagia for fifteen days, probably on account of the high altitude to which she had recently moved. She attempted to relieve this condition by drinking a concoction made from two grated nutmegs and a pint of water. She drank about one-quarter of this mixture after eating breakfast, and was soon overcome by drowsiness which passed into a deep sleep. She awoke about six o'clock at night, when she ate her supper and drank the rest of the concoction. From the stupor which followed, she was aroused with difficulty. The attendants resorted to slapping, passive movements, and the administration of three or four ounces of brandy. She was slightly delirious, the respirations were 42, with prolonged inspiration and shallow expiration, the pulse was weak and irregular and over 140, the extremities were cold and cyanosed, and the pupils reacted slowly to light. The writer gave her strychnine sulphate, $\frac{1}{30}$ gr. by hypodermic injection, repeated in an hour. Half an hour after the second dose, both delirium and dyspnœa had disappeared, the pulse was 102 and regular, but there was extreme muscular weakness. Strychnine sulphate was continued in $\frac{1}{60}$ gr. doses by the mouth every two hours. The recovery was rapid and uneventful. The menorrhagia ceased that night, and menstruation was normal the following month.

The Medical News, November 2, 1901.

An Interesting Accident of Staining.—J. O. Cobb calls attention to the crystals formed by the use of methyl which he has at times used instead of methylene blue, as a contrast stain in working with sputum. When the crystals were first noticed, they were supposed to be accidental air bacilli. The presence of carbolic acid and heat produce beautiful crystallization, and fresh preparations of the stain give crystals much more uniform in size and much smaller than in old preparations. An albuminoid substance seems to be necessary to the production of the crystals. The writer then speaks of the accident of staining with Sudan III. In working with sputum of a doubtful case, Sudan III must not be relied upon, as it deposits crystals which closely resemble the bacillus.

Experimental Tuberculosis of the Suprarenal Capsule in Relation to Addison's Disease.—Bindo de Vecchi has developed experimental tuberculosis in the suprarenals with a view to studying its effects on the general organism. The animals used in these experiments were male and female rabbits, both white and colored. The injections were made on one or both sides, in one or two operations. If there were no complications, and the animal did not succumb to the immediate effects of the operation, life continued for three and one-half to four months. During this time no alteration in the color of the skin or mucous membranes was ever noticed, nor was there any dystrophy of the fur. There seemed to be a general loss of appetite; in some cases tremor and paresis of the hind limbs developed, and the fur became ruffled. There was a loss of 30 per cent. in weight, a little rise in temperature occurred, and a progressive decrease in the number of red cells was observed. Thus it appears that by inducing tuberculosis of the suprarenals, a serious poisoning of the rabbits is produced, which finally leads to their death. There were degenerative changes in the heart, liver, and kidneys. The cells of the central nervous system showed themselves to be particularly vulnerable; there were grave changes in the gray matter, especially in the nerve-cells themselves, in which there was an increase of the pericellular lymphatic spaces, sometimes with the presence of corpuscles, probably leucocytic in character, swelling and thorny appearance of the cells, abnormal position of the nucleus, with disappearance of the chromatic network and the pseudonucleoli; the nucleolus moved to the outside, and advanced chromatolysis of the protoplasm developed; the bodies of Nissl appeared to be pulverized with broken or varicose prolongations. The nerve-cells in the posterior part of the spinal cord were entirely changed, and the pericellular and perivascular spaces were filled with red cells and leucocytes. The writer adds that all these lesions in his opinion must not be attributed to changes in the sympathetic system, but to a general intoxication with tubercle toxin. No injury of the white nerve substance could be discovered. The solar plexus, the splanchnic nerves, and the cervical and thoracic chains of sympathetic ganglia were normal. In only one case was the cœliac ganglion altered by the tuberculous process. There was no important alteration of the bowels. The capsules were in partial or complete caseation. The injuries to the cells of the central nervous system explain the nervous symptoms of those suffering from Addison's disease. The lungs, alimentary tract, pituitary gland, thyroid, and ovaries were normal. From the decrease in red blood cells and the activity present in the bone-marrow, it may be concluded that the capsules possess hæmolytic properties.

Philadelphia Medical Journal, November 2, 1901.

Observations on the Treatment of Croupous Pneumonia.—James C. Wilson describes the following treatment: The diet consists chiefly of milk and light broths, junket, custard, and gruels, a little ice cream, and sometimes raw or stewed fruits may be given. The amount should be small. Water is given in abundance, not more than two ounces at a time. In ordinary cases, the patient is given a morning and evening sponge, with water the temperature of which is regulated by the sensations. Early in the attack, several large flat ice-bags are applied to the affected side. Alcohol is given in most cases. A calomel purge is commonly administered at first. This is repeated once or twice during the attack. If there is great pain, morphine is given by hypodermic injection; in any case Dover's powder is administered every two or three hours throughout the greater part of the course of the attack. Expectorants are rarely used. Digitalis is sometimes given when the pulse is small and frequent, but often strophanthus is better. For weak heart, strychnine and the nitrites or venesection are employed. Atropine is used for pulmonary œdema. Dyspnœa demands oxygen. Ice to the head is useful in delirium. The patient wears a moderately heavy, loose-fitting merino undershirt. At the crisis the patient is carefully watched. Collapse is rare. During convalescence an abundant nutritious diet is given. Bitter tonics are sometimes employed.

The Influence of Secondary Infections in Chronic Pulmonary Phthisis.—Alexander G. R. Foulerton calls attention to the pathological difference between chronic pulmonary tuberculosis and chronic pulmonary phthisis; the bacillus tuberculosis is present in the lesions of each, but in uncomplicated cases of the former, the single kind of organism is present, and generally manifests but a low degree of virulence, while in phthisis there is added to this the more potent influence of pyogenic organisms. It is to the pyogenic cocci, particularly to the streptococcus pyogenes, that we must look for the effects of secondary infection. The effect of secondarily infecting organisms has to be considered only with regard to their local action and with regard to the production of a toxæmia. When secondary infection by pyogenic bacteria is absent, constitutional symptoms indicative of any serious toxæmia are wanting. With the increase of the pyogenic organisms, there is a development of physical signs in the chest, wasting, night sweats, and high evening temperature. This has been observed in careful examinations of sputum. Secondary infection is the chief, or at any rate the immediate, cause of the excessive mortality from pulmonary phthisis. The secondary infections should be the chief object in the treatment of this disease. The writer believes that ultimate success in the specific treatment of declared tuberculosis will be attained with some modification of tuberculin, and he also thinks that the comparative failure of the method in the past has been almost entirely due to the ignoring of the effects of secondary infection of the lung lesions by pyogenic cocci. The patient so afflicted should be kept in an atmosphere of practically germ-free air, such as may be found at moderate altitudes, while the nearest approach possible to complete physical rest should be ordered. Besides this, it is likely that a systematic treatment with antistreptococcic serum in cases in which the streptococcus pyogenes is the predominating organ-

suitable these cases form a large proportion of the whole—would materially help in shortening the time which must elapse before any specific treatment for the tuberculosis can be safely attempted

The Lancet, October 26, 1901.

A Case of Urticaria Following Immediately on Wasp-Sting.—The patient of T. W. Parry was a boy of fifteen years who was stung by a wasp on the finger and who developed urticaria all over the body with the usual symptoms. The author regards the case of special interest, first, because general eruptions are exceedingly rare after wasp-stings; and second, because the suddenness of the onset of the rash, after the sting had been inflicted, is also peculiar and seems to be indicative of a hypodermic injection of some toxic substance which might have been imparted with the sting. May it not be within the range of probability, he asks, that there is in existence an urticaria-producing bacillus which may take its place among those myriads of bacilli which, though at present "undiscovered," are suspected of being the causation of certain so-called "idiopathic affections?"

A Case of Compound Fractures of Both Jaws.—The patient of H. Weighton was a young man who fell from his bicycle while descending a steep hill. There was a complete fracture of the lower jaw near the symphysis and also detachment of a part of the alveolus in front containing three teeth. There was further a fracture of the upper jaw at each side in the region of the canine teeth but with little displacement or deformity. The whole premaxilla could be easily moved about. The fractures were treated temporarily by wire passed between the teeth on each side, the whole being fixed with an external gutta-percha splint fitted to the chin and a [illegible] bandage. Next day a dentist made a snug [illegible] mould, in the center of which was a hole [illegible] a feeding tube could be introduced. This [illegible] was removed in five weeks, and firm union [illegible]

Acute Dilatation of the Stomach.—H. C. Thomson says [illegible] dilatation of the stomach is probably allied [illegible] and nature to the paralytic distention [illegible] intestines which frequently occurs after severe [illegible] operations, and also in inflammatory conditions [illegible] the peritoneum. At present, there seems no adequate explanation as to why the intestines should be [illegible] in some cases and the stomach in others, though most likely this depends on the difference in reaction to stimulation of the several nerve ganglia. It is possible that some cases occurring after operation are due to the effect of the anæsthetic upon the nervous system. Treatment of recorded cases seems to have been of little avail. The passing of a tube into the stomach has given but temporary relief. Reliance should be placed on rectal feeding, and the tendency to collapse may be combated by hypodermic injections of strychnine. Some of the more serious symptoms are undoubtedly due to the loss of large quantities of fluid, and saline solution should be used either by enema or transfusion.

The Acute Retropharyngeal Abscesses of Infants. S. V. Paterson reports eight cases. His mode of operating is thus stated. The position of the incision should be immediately behind, and parallel to, the sternomastoid, its center should be as nearly as possible on the same level as the center of the swelling behind the pharynx, or a little below this. Toward the bottom of the wound the spinal accessory nerve must be avoided. Having used a knife to cut through skin and fascia, the posterior edge of the sternomastoid being carefully exposed and the muscle pulled slightly forward, the knife should be abandoned in favor of a blunt dissector and a pair of dissecting forceps. By the time this stage of the operation has been reached it may have been necessary to remove one or two slightly enlarged glands situated behind the sternomastoid. From this time onward the operation consists in a careful separation of the structures until the prevertebral region is reached. The landmarks are the transverse processes and the plane of the anterior surface of the vertebral bodies. Keep well back, feel with the finger for these landmarks, and there will then be no danger of injuring the jugular vein or cervical sympathetic, the only two structures likely to be interfered with. The patient should never be at all deeply under anæsthesia, but at this stage of the operation he should be allowed to come round partially. Then matters are much facilitated by introducing one finger into the mouth and a finger of the other hand into the wound. By this means the exact limits of the abscess cavity can be made out. Then a fairly fine-pointed blunt dissector or similar instrument can be passed along the front of the finger in the wound, and the abscess so pierced. The pus flows out readily when the opening is made larger by means of a pair of sinus forceps guided into the cavity by the instrument already introduced. It is important to remember that the finger of one hand has been introduced into the mouth, and this should not touch the wound until it has been again sterilized. The cavity must be irrigated once or twice with some antiseptic solution. Then a very small drainage-tube should be introduced down to the greatest depth of the wound, and a small strip of gauze may be wrapped around this superficially. One or two stitches are then put in to bring the edges together above and below the tube, and an ordinary antiseptic dressing is applied.

British Medical Journal, October 26, 1901.

The Means of Arresting Acute Endocarditis.—G. H. Youngé advocates the combined use of blisters and poultices in the earlier stages of acute endocarditis, when pain is a marked symptom. A blister is fixed with adhesive plaster over the place where pain is most severe. A large linseed-meal poultice, as hot as can be borne, is applied over the blister and changed as often as necessary. The blister is punctured and dressed, and then a thick layer of cotton wool or spongiopiline is placed over the entire surface to prevent any chill.

Primary Chancre of the Tonsil.—W. H. Kelson reports a case with the history that after tonsillotomy one side never got properly well, enlarged glands appeared at the angle of the jaw, and in due time the patient showed the typical signs of secondary syphilis. The writer believes that infection occurs in the following ways: Either hereditary syphilis may be overlooked in a child, or if a young adult with large tonsils seeks advice for what is really an incipient specific throat it often happens that tonsillotomy is performed and the syphilitic character of the disease is not recognized. Thorough sterilization is the moral.

A Discussion on the Role of Toxic Action in the Pathogenesis of Insanity.—W. Ford Robinson concludes that by far the most important factor in the pathogenesis of insanity is toxic action. The large majority of cases of insanity are not primarily diseases of the brain at all, but are dependent upon the action of toxins formed elsewhere, which affect the functional activity of the cortical nerve cells by disordering their metabolism and often permanently damaging or even destroying many of them. The common view that the "mental disease" is the primary condition, and that any accompanying bodily disease is secondary, is generally founded upon an erroneous conception of what is taking place. Insanity must be regarded as a disease of the whole organism.

Note on the Results Obtained by Antityphoid Inoculation in the Case of an Epidemic of Typhoid Fever. A. E. Wright reports the following results which have been calculated upon the average strength of the individuals composing the groups of inoculated and uninoculated individuals in the Richmond Asylum of Dublin. The period of time considered is that intervening between the commencement of the inoculations and the termination of the epidemic. The daily strength was calculated as follows. Each case was multiplied by the number of days during which that particular strength was maintained; the figures in each group were then added together and divided in each case by the number of days included within the whole period of observation. In this manner, the result was reached of a daily average strength of 339 for the inoculated, and of 208 for the uninoculated. On this basis, the number of cases among the uninoculated was thirty, among the inoculated, five. The percentage of cases is thus, 10.1 for the first group, and 1.5 for the second. The number of deaths in the first group was four, a percentage of 1.3; in the second group, the number was one, a percentage of 0.3. The writer states that this result is in conformity with that of all the statistical returns of antityphoid inoculations that have reached him.

Colitis or Asylum Dysentery? Thomas Claye Shaw states that in the absence of a definite bacillus, it would seem that in nerve degeneration there is the very condition required for the growth and development of bacteria, and as insane persons are already in a state of reduction, this is a probable reason for the diarrhœa and colitis so often found in asylums. Certain recent observations make it not improbable that recurrent attacks of insanity are due to some recurring condition of the blood of a toxic nature. The writer thinks it quite possible that the intestinal ulceration which without doubt does occur in some of the insane, may be also due to some toxic condition which develops in the patient. If a special bacillus exists for dysentery, it has not been isolated. The writer adds that he does not believe that any asylum exists in which ulceration of some part of the intestines is not occasionally found. But it is quite

independent of overcrowding, and according to the writer's belief it does not depend on the food, on the sewage farms, on the habits of the patients, or always on the presence of a bacillus of a particular type. He believes that there is a degeneration of the mucous coats of the intestine due to nerve degeneration, and that pathogenic organisms may be and are generally present in these cases, but no specific germ has been isolated. The probable order of events is: degeneration, owing to lowered vital tone, and then the presence of bacterial due to this catabolic state.

Münchener medicinische Wochenschrift, October 15, 1901

The Value of Methodical Deep Breathing, Especially in Sea-Sickness.—M. Kaufmann, like Heinz, who recently published some observations in the same journal, has found deep inspirations a great aid in warding off sea-sickness. He also recommends the measure in various other contingencies of practice, and as the tendency to syncope, collapse after hemorrhage, particularly in labor cases, epistaxis, singultus, etc. In such cases the effect is due mainly to improvement in the circulation depending on increased activity of the respiratory center, though the psychical effect produced by the mental concentration required is also important.

Why Does Gelatin Act as a Hemostatic?—Zibell analyzed four specimens of gelatin and found that the most constant constituent was calcium, the average amount present being 0.6 per cent. In 100 c.c. of a 5-per-cent. solution this would correspond to 0.03 gm. of calcium—a not inconsiderable dose, particularly when it is considered that in this form it is very soluble and therefore very absorbable. The action of calcium salts in hastening coagulation is well known, and, in the absence of more definite knowledge, it seems highly probable that the gelatin owes its hemostatic properties, when given subcutaneously, to the calcium that it contains.

Two Cases of Foreign Body in the Tympanic Cavity.—Holscher adds two more to the list of casualties produced by unsuccessful attempts at the instrumental removal of foreign bodies from the ear. Both patients were children; in the one case the offending object was a cherry pit, and in the other a small pebble. The unsuccessful manipulations had finally forced the foreign bodies through the drum membrane into the tympanic cavity, whence they could be removed only by a radical operation. The general practitioner should always confine his efforts to the use of the syringe, which in most cases will produce the desired effect. Even bodies likely to absorb water and swell may be attacked in this way, and if they are not immediately removed, further swelling may be prevented by pouring warm alcohol into the ear.

An Unusual Case of Tuberculosis of the Trachea, Associated with Tracheal Varicosities and Ending Fatally.—Gidionsen describes the death from sudden hemorrhage of a middle-aged woman who gave the physical signs of extreme emphysema, but no evidence of tuberculosis. On autopsy, the posterior wall of the trachea was found covered with dilated veins, and in the middle of this area was an ulcerated patch which was subsequently shown to be of tuberculous origin. The assumption is that one of the dilated veins having been eroded, the trachea and main bronchi immediately filled with blood, which the very emphysematous lungs could not expel, and death therefore resulted from suffocation. Primary tuberculosis of the trachea is rare, and as all the organs could not be examined, it is doubtful whether even this case is to be regarded as such.

Deutsche medicinische Wochenschrift, October 17, 1901.

A Case of Epidemic Parotitis of Unusual Severity.—E. Schwarzkopf describes a case of mumps presenting features of unusual gravity. During an epidemic of the disease a man of twenty-nine years was brought in who, after several chills, headache, and vertigo, developed the typhoid state. A little later the gland began to swell, and at the same time diarrhœa with pea-soup stools set in. For a time it seemed possible that the case was one of typhoid fever with parotitis as a complication, but defervescence on the ninth day with rapid convalescence settled the question of diagnosis.

A New Method of Treatment of Carcinoma.—F. Loeffler calls attention to some observations by older clinicians that the supervention of a malarial infection can cause the disappearance of cancerous growths. He also says that malignant disease is very rare in the tropics, where malaria is common, and suggests that by carefully controlled inoculations it may be possible to use the malarial organism as a remedy for at least some forms of carcinoma. In conclusion, he invites observations from medical men in the tropics on the comparative frequency of the two diseases, and urges clinical tests of the method.

Further Contributions on the Differentiation of Human and Animal Blood by the Aid of a Specific Serum.—E. Ziemke publishes further observations on this subject which corroborate the conclusions of other observers. In attempting to simplify the reaction for practical use, he experimented with serum obtained from cadavers, and found that when taken within four days of death a product can be secured which does not infect the animals used, and is active to the degree required by Uhlenhuth's postulate that in a strength of one to thirty a distinct clouding shall take place in yellowish blood solutions. Experiments with hydrocele fluid and with pleural exudate gave positive reactions, rather a remarkable result when it is considered that the latter was more than a year and a half old. Various efforts to produce a preparation which might be kept indefinitely and serve as a stable reagent for forensic use gave encouraging, but not wholly satisfactory, results. The observation was also made that the admixture of blood of other species from that examined did not interfere with the reaction.

French Journals.

Movable Kidney.—Guillet collects the various theories concerning the pathogeny of movable kidney under three headings: 1. An anatomical lesion of the kidneys or of the neighboring organs. 2. Physiological cause. 3. A general laxity of construction of the individual organism. As to the conditions indicating operation, the writer concludes: There should be no operation on movable kidneys which cause no trouble, the use of a bandage being sufficient. Operation should be performed on those which are the seat of a neoplastic or inflammatory degeneration, such as hydronephrosis, pyonephritis, etc., the operation being suited to the individual case. Recourse should be had to nephrorrhaphy for painful movable kidneys, and for those which cause digestive troubles, when it is clear that the pain and digestive troubles are due to the displacement of the kidney. In these cases the effect of a bandage may be tried before operating. The symptoms which force the patient to seek medical advice fall into three categories, viz., pain, which is the most common, neurasthenic symptoms, and dyspeptic symptoms.—*La Policlinique Médicale*, October 26, 1901.

Aneurysm of the Mesenteric Arteries.—Louis Gallavardin states that two periods in the symptomatology of this affection can be distinguished: a period of evolution of the tumor, and the terminal period or the rupture. The first period varies greatly according to the patient. The tumor is sometimes absolutely latent, but more frequently there are some pains or obscure abdominal symptoms. In certain cases the pains are sharp, resembling in their violent and paroxysmal character the painful crises of aneurysm of the aorta. The tumor has rarely been perceived. The tumor may compress the neighboring organs. The patient may die before the rupture of the tumor from endarteritis (the causal malady), or some intercurrent affection. Rupture is, nevertheless, a frequent termination. It is remarkable that in the cases noted death has not been sudden, but only rapid. There are violent abdominal pains, followed by nausea and vomiting. The patient becomes pallid and dies sometimes after several hours. The diagnosis of this affection is almost impossible in most cases. Autopsy generally discloses the true state of affairs. The superior mesenteric artery is nearly always the one affected.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, October 13, 1901.

Surgery of the Spleen.—Février enumerates as surgical affections of the spleen: traumatism, abscess, tumors (including cysts and hypertrophies), and displacements. In subcutaneous ruptures the spleen may be reduced to pulp, or it may be only lacerated. The diagnosis of subcutaneous rupture is easily made from the symptoms of internal hemorrhage, with localization of pain in the left hypochondrium, especially if there are external signs of traumatism in the region of the kidney. Abdominal contraction is a striking sypmtom. Various methods of treatment have been tried, such as extirpation of the kidney, tampon, suture of the splenic wound, ligature of the vessels of the pedicle, and laparotomy, pure and simple. Diagnosis of abscess of the kidney is surrounded with difficulties. When it is once established, the abscess should be incised. The treatment of tumor of the kidney is varied and depends upon the nature of the growth. One growth, perhaps worthy of special mention, is tuberculosis of the kidney. The most frequent form is the sclerocaseous. The lesion resembles tuberculosis ganglia. The best surgical treatment is splenectomy. In displacement of the spleen, there are two methods of treatment: The spleen may be extirpated, or it may be sutured in position. The choice of the method will depend upon the individual case.—*La Presse Médicale*, October 23, 1901.

Book Reviews.

SURGICAL TECHNIC: A Textbook on Operative Surgery. By FR. VON ESMARCH, M. D., Professor of Surgery, University of Kiel, Surgeon-General of the German Army, and E. KOWALZIG, M.D., late First Assistant at the Surgical Clinic of the University of Kiel. Translated by Professor LUDWIG H. GRAU, Ph.D., and WILLIAM N. SULLIVAN, M.D., Assistant at the Surgical Clinic at Cooper Medical College, San Francisco. Edited by NICHOLAS SENN, M.D., Professor of Surgery, Rush Medical College, Chicago. With 1,497 illustrations, and fifteen colored plates. New York: The Macmillan Co.; London: Macmillan & Co., 1901.

WE gather from the two American prefaces of this large volume that the translators and the editor believe that they have rendered a great service to American surgery. The number of our own publications is so large and their quality so high that no great benefits are apt to be conferred by the translation of a foreign work, though the present volume will afford an opportunity for those who are not familiar with German to read the work of one of Germany's foremost followers of this department of medicine. The idea of the work is to offer an encyclopedic though concise treatise upon the whole field of operative surgery, and this intention has been furthered by the use of many illustrations and comparatively little text. In the first part of the book, the subject of the treatment of wounds and injuries in general is given, and in this is included the subjects of bandaging and splints. As would be expected, emergency and military surgery receive full discussion, especially the emergency treatment of wounds. The chapters devoted to amputations and resections are satisfactory enough, and the illustrations, though not of high quality, serve their purpose. Abdominal operations are described briefly, and many of the technical procedures upon the abdominal organs are illustrated; but it is almost impossible in a work of this kind to do justice to such highly specialized subjects. Those who wish a book of reference upon operative surgery will find this volume useful, but not indispensable. The colored plates are good, but the other illustrations are apparently from old plates, and are poor, according to present-day standards. The translators have done their work well.

ATLAS AND EPITOME OF SPECIAL PATHOLOGIC HISTOLOGY By Docent Dr. HERMANN DURCK, of the Pathologic Institute of Munich. Edited by LUDWIG HEKTOEN, M.D., Professor of Pathology in Rush Medical College, Chicago. Vol. II. Liver; Urinary Organs; Sexual Organs; Nervous System; Skin; Muscles; Bones. With 123 colored illustrations on 60 lithographic plates. Philadelphia and London: W. B. Saunders & Co., 1901. Cloth, $3 *net*.

THIS, the second volume upon Special Pathologic Histology in the Saunders Series of Handatlases, deals with the liver, pancreas, urinary organs, male and female sexual organs, central nervous system, muscles, skin, bones, and joints, and, with the preceding volume, completes the subject. Concerning both text and illustrations, nothing but praise can be said.

The former, while concise, is adequate, and is notably clear and accurate. The volume is illustrated by 60 colored lithographic plates which are admirable in drawing, and which reproduce in a really beautiful way the appearances of the stained sections.

All the more important lesions are dealt with in a systematic and thorough way, and the little volume will be found valuable, not only to students of medicine, but to all who wish to familiarize themselves with the microscopic appearances of morbid processes.

A TEXTBOOK OF BACTERIOLOGY. By GEO. M. STERNBERG, M.D., LL.D., Surgeon-General United States Army, ex-President of the American Medical Association and of the American Public Health Association; Honorary Member of the Epidemiological Society of London, of the Royal Academy of Medicine of Rome, of the Academy of Medicine of Rio de Janeiro, of the Société Française d'Hygiene, etc., etc. Illustrated by Heliotype and chromo-lithographic plates and two hundred engravings. Second revised edition, 708 pages. Muslin, $5.00; sheep, $5.75. New York: William Wood & Co., 1901.

AT the request of the publishers the author has revised and now edits what is practically the third edition of his "Manual of Bacteriology," although the title was altered when the second issue appeared as a more practical textbook.

The most notable changes are the chapters on Protective Inoculations in Infectious Diseases and on the Bacteria of Plant Diseases, both of which are new and contain practically all that has been determined upon the subjects. The most notable of the experiments are mentioned and the latest theories discussed. About one hundred pages are devoted to Protective Inoculations, while a much shorter résumé of Plant Bacteria will prove of interest to those working in Agriculture and allied pursuits.

In order to allow the work to be published in one volume, the new knowledge has compelled the omission of descriptions which dealt with uncommon or imperfectly studied varieties, but nowhere has it forced out what is practical or vital.

The work has been so well received by those interested in bacteriological research here and abroad that it seems unnecessary to praise it. Still, it must be admitted that it fulfills every requirement for the student, practitioner, and advanced worker in pathogenic bacteria. The presswork, colored plates, engravings, and binding, all add to a text which employs smooth English, and imparts knowledge, clearly, compactly, and with discrimination.

As a laboratory guide and a companion for scientific medicine we know of no better book on the subject treated, and of no better authority from which to draw information concerning results obtained in this extremely active field.

LIBERTINISM AND MARRIAGE. By Dr. LOUIS JULLIEN, Surgeon of Saint-Lazare Prison; Laureate of the Institute, of the Academy of Medicine, and of the Faculty of Medicine of Paris. Translated by R. B. DOUGLAS. Philadelphia: F. A. Davis Company, Publishers, 1901.

WERE we asked what means, other than legislative acts, would tend to prevent the marriage of a diseased couple (be it the male or the female), we would unhesitatingly say that an extensive distribution of this admirable work of our French colleague would absolutely serve the purpose. This treatise is the forerunner of the literature which is bound to come, in order to educate the masses that the nuptial bed is but, in many cases, the sick bed of the future wife and mother. The main object of the author is to bring before the reading medical public the awful result of the combination of libertinism and marriage. How well and clearly he puts his words is shown on every page; sad always; but occasionally the flippant humor of the Frenchman crops out in the attempt to paint the embarrassment either of the guilty lover or the not overparticular wife or the adventurous husband who is caught in or after the act with its dire consequences. Our duty, as the author properly claims, is not alone to cure, but to prevent on the one hand, as well as to instruct the young people, both male and female, on the other. His words are as follows: "The campaign must be carried on without respite, until every class of society is aware of the dangers. When we have attained that end, the problem will be nearly solved; for, on the one hand, young people will seek every means of cure, and on the other hand, parents will awake to a danger formally considered as non-existent or illusory, or in any case quite negligible, and they will not omit to make inquiries on the subject. They will then be our best allies." This, in a nutshell, is the author's position, and any rightminded thinker must agree with him. We commend this book, not alone to medical men, but to the great laity.

HUMAN PHYSIOLOGY. Prepared with Special Reference to Students of Medicine. By JOSEPH HOWARD RAYMOND, A.M., M.D., Professor of Physiology and Hygiene in the Long Island College Hospital, and Director of Physiology in Hoagland Laboratory, New York City. Second edition. Philadelphia and London: W. B. Saunders & Co., 1901.

THE first edition of this work enjoyed the reputation of being an excellent textbook of physiology for students' use. The author's style was clear and his descriptions were lucid and accurate. In the present edition, the changes, while extensive, are not such as to alter in any respect the character and general plan of the work. A section on histology has been added, and in certain topics upon which discussion is still going on, such as the origin of uric acid, the neuron theory, the relation of menstruation to ovulation, alcohol, etc., the author has added a description of the progress that has been made in the direction of this solution of the existing problems.

EXPERIMENTELLE UND KRITISCHE BEITRÄGE ZUR HÄNDEDESINFECTIONSFRAGE. Von Dr. RICHARD SCHAEFFER in Berlin. Berlin: S. Karger, 1902.

IN this brochure of a hundred pages, the author gives in résumé the results of the elaborate work lately done by Paul, Kronig, Sarwey, Blumberg, and others, and after a consideration of the possible fallacies of their methods

describes his own experiments. These are sufficiently encouraging to indicate that the pessimistic views prevalent on the subject of hand disinfection are overdrawn, and that it is possible to reduce the bacterial flora of the hands to such a degree as to make danger of infection from this source very slight indeed. The method that gives best results is the hot-water-soap-alcohol process, which is superior to the procedures depending mainly on chemical disinfection.

PATHOLOGICAL TECHNIQUE. A Practical Manual for Workers in Pathological Histology and Bacteriology, Including Direction for the Performance of Autopsies and for Clinical Diagnosis by Laboratory Methods. By FRANK BURR MALLORY, A.M., M.D., Associate Professor of Pathology, Harvard University Medical School; and JAMES HOMER WRIGHT, A.M., M.D., Instructor in Pathology, Harvard University Medical School. Second edition, revised and enlarged, with 137 illustrations. Philadelphia and London: W. B. Saunders & Co., 1901. Cloth, $3 *net*.

THAT a second edition of this most excellent handbook of pathological technique should be so soon required furnishes another illustration of the rapidly growing appreciation by the profession at large of the value of pathological examinations in practical clinical work.

The book has been somewhat enlarged, chiefly by additions to the sections on bacteriological methods. The appearance of a number of new and beautiful microphotographs of bacteria and other microorganisms is especially to be noted. The description of the parasite of actinomycosis is much amplified, and there have been added descriptions of the bacillus of bubonic plague and of the parasite of mycetoma as well as of a number of improved methods of histological technique. Altogether, this book fills more completely than any with which we are acquainted the requirements of a laboratory guide in practical pathology and bacteriology.

MANUAL OF CHEMISTRY. A Guide to Lectures and Laboratory Work for Beginners in Chemistry. A Textbook Specially Adapted for Students of Medicine, Pharmacy, and Dentistry. By W. SIMON, Ph.D., M.D., Professor of Chemistry in the College of Physicians and Surgeons of Baltimore, in the Maryland College of Pharmacy, and in the Baltimore College of Dental Surgery. Seventh edition. Philadelphia and New York: Lea Brothers & Co., 1901.

THIS work has been so long in existence as a textbook, and has been used by so many now long since graduated, who know its merits from practical experience, that little beyond repetition can be said of this new edition. The work has been brought thoroughly up to date, and much valuable material has been added in the parts on physiological chemistry and chemical physics. The aim of Dr. Simon in the successive editions of his book has been "to furnish to the student in concise form a clear presentation of the science, an intelligent discussion of those substances which are of use to him, and a valuable guide to his work in the laboratory." A careful examination of the book convinces us that the author has well accomplished this object.

THE AMERICAN ILLUSTRATED MEDICAL DICTIONARY. A New and Complete Dictionary of the Terms Used in Medicine, Surgery, Dentistry, Pharmacy, Chemistry, and the Kindred Branches, with their Pronunciation, Derivation, and Definition, Including Much Collateral Information of an Encyclopedic Character. By W. A. NEWMAN DORLAND, A.M., M.D., Assistant Obstetrician to the University of Pennsylvania Hospital; Editor of the American Pocket Medical Dictionary; Fellow of the American Academy of Medicine. Second edition, revised. Philadelphia and London: W. B. Saunders & Co., 1901.

IT is strange to find that, with all the competition that exists in the medical-dictionary manufacture, the products of nine dictionary builders coming out in a period of about twelve years—the latest has found sale enough to exhaust an edition in less than a year. The only explanation of this fact that occurs to us is that none of the existing works is satisfactory in all respects, and so each new one that appears attracts purchasers among those who still hope to find something really good. Another explanation of the success of Dr. Dorland's book is perhaps that it is an improvement over the one upon which it is modeled—an improvement in size and convenience of handling, in typography and illustrations, and in accuracy. In this second edition the author says he has added about one hundred important new terms that have appeared in medical literature during the past few months, which is curious testimony to the rapidity with which medical science is progressing.

Clinical Department.

GUNSHOT WOUND OF THE ABDOMEN.

TEN INTESTINAL PERFORATIONS FROM PISTOL BULLET—RESECTION OF TWENTY-FOUR INCHES—ANASTOMOSIS BY MURPHY'S BUTTON—RECOVERY.

By D. E. BLOOD, M.D.,
FAIR HAVEN, WASH.
AFTERWARD PHYSICIAN TO ST. LUKE'S HOSPITAL, ASSISTING SURGEON TO ST. JOSEPH'S HOSPITAL.

THIS case is believed worthy of record, on account not only of the severity of the injury, but also of the age of the patient.

J. N., aged fifty-seven, American, a logger, was shot in the abdomen during a street brawl on May 20, 1897. After being shot, he ran a distance of forty yards to shelter himself behind a wagon, his assailant firing three or four more shots, without effect, before being taken into custody. Then, without aid, he walked about the same distance toward my office and upstairs to the first landing, when, with the assistance of a man on either side, he walked into the office and lay down upon a sofa.

A hasty examination showed a gunshot wound midway between the umbilicus and pubes, two inches to the left of the median line. He was suffering from a moderate degree of shock and was given a hypodermic of morphine gr. $\frac{1}{4}$ and atropine—$\frac{1}{150}$. As it seemed certain that a wound of this sort (38 caliber, fired at the distance of only a few feet) could not be other than penetrating, with probable injury to the intestines or other viscera, it was thought advisable to send him to St. Luke's Hospital, only a few blocks distant, for an exploratory operation. On account of the medico-legal aspect of the case, operation was delayed until the County attorney could be sent for, and the statement of the patient taken, which consumed considerable time. I was assisted by Drs. H. A. Compton and H. E. Henderson, chloroform being skilfully administered by Dr. Axtel. Drs. Kelly, Appleby, and Van Zandt were present.

A median incision was made, extending from an inch below the umbilicus to the same distance above the pubes. The ball was found to have passed upward, backward, and toward the right side, probably burying itself in the thick lumbar muscles of that side. It was not found, nor was an exhaustive search made for it. An examination of the small intestine showed ten perforations, one at the mesenteric attachment, causing considerable hemorrhage. It was hoped at first that the perforations might be situated so that they could be closed by Czerny-Lembert sutures, but the intestine was damaged so badly that this procedure would in two places have caused serious narrowing of the lumen of the gut. The lowest perforation was about three feet above the ileocæcal valve, and the highest nearly two feet above this point. Accordingly, the entire damaged segment, measuring twenty-four inches, was resected and an end-to-end anastomosis made by Murphy's button. The abdominal cavity was carefully sponged out and then irrigated with sterilized hot salt solution, and the incision closed by a single layer of silkworm-gut sutures.

Combined tubular and gauze drainage was used and removed in forty-eight hours. Time of operation, one and one-half hours. The man made a slow but very satisfactory recovery, his temperature only at one time going to 100½, this being due to a stitch abscess. An annoying complication after about ten days was a cystitis, due no doubt to lack of care in cleansing the catheter, although an unusually long prepuce and a moderately hypertrophied prostate made it difficult to avoid. The but-

ton passed on the thirty-sixth day, and the patient left the hospital on the forty-second day, with a good cicatrix, his bowels moving regularly and without difficulty.

Eight months later he was in good health and able to appear in court to defend a suit for collection of the fees in the case. And later, it is alleged, he eloped with the ex-wife of the man who shot him, and who has since borne him an heir.

SULPHUR IN THE TREATMENT OF CARBUNCLES AND BOILS.

By G. HARDY CLARK, M.D.
WATERLOO, IOWA.

Since 1893, following the publication of W. Arbuthnot Lane's articles in the *Lancet* upon the subject, sulphur has found occasional place in general surgery. After using it for almost a decade in every case of carbuncle or boil that has come to me, and finding its curative effects immediate and painless, I feel free to direct the attention of the medical profession to its use in this condition.

The pathogenic agent in carbuncle and boil causes a necrosis of the areolar tissue, together with sclerotic and deliminating processes, and it is only after the local destructiveness of this agent has been largely expended that the pus cocci operate to extrude the necrotic mass. In the experience of the writer this drug will compass the destruction of the materies morbi as well as the purification of its products within six or eight hours, and resolution will then occur with little or no assistance from pus-producing cocci. The wonderful facility with which sulphur products permeate the tissues of the body has led practitioners to rely upon large doses of the sulphide of calcium and the sulphates of magnesia and iron to cure carbuncles and boils to the exclusion of all surgical procedure. How much more effective this drug can be when placed in immediate contact with the diseased tissues must be tried to be appreciated. The moist surfaces rapidly transform it into sulphurous acid, sulphuretted hydrogen, and sulphuric acid, which, by preventing the further destruction of tissue, limit the extent of the resultant scar.

The technique of the little operation consists in making a free crucial incision under local anæsthesia, loosening the tissues in a measure from the underlying fascia with a strong director and packing the wound carefully and completely with a strip of gauze thoroughly filled with precipitated sulphur. Over the wound is placed a pad of wet gauze or absorbent cotton, and the whole is covered with a piece of gutta-percha tissue, and held in place by a roller bandage. In from six to eight hours the dressing is removed, and the wound is cleansed and redressed with Thiersch's solution, boroglyceride, or other antiseptic under the protective and roller bandage as before.

MULTIPLE DISSEMINATED SUBDERMAL NODULES.

By MARK A. RODGERS, M.D.
TUCSON, ARIZONA.

I have recently encountered in my practice in this city a very peculiar case, which I would like to bring before the medical profession for the purpose of having some assistance in the matter of diagnosis. The case is that of a young Mexican woman, aged twenty-two, who has resided on a ranch, about forty miles south of this city, during her lifetime. About three years ago, she began to have nodular swellings in the regions of the articulations; these were associated with considerable pain, some disturbance of digestion, slight fever and general malaise. The nodules gradually increased in size, and then at times the size diminished somewhat, but the nodules never wholly disappeared. On the whole, there has been a general increase in size of all of the nodules, and also an increase in their number. The nodules resemble, in some respects, the lesions of erythema nodosum, but seem to be subdermal. They are largely in the vicinity of the ends of the long bones, but are generally distributed all over the body, even on the scalp. The nodules range from the size of a small nut to almost that of a hen's egg. They are fluctuating and well outlined, and seem almost as if they were enclosed in a serous sac. On opening one of them, a peculiar greenish-tinged serum exuded, which continued to flow for several days. Then the opening closed, and the nodule reappeared under the skin. There has been at no time any discoloration such as one might expect in a case of erythema nodosum. There is absolutely no pigmentation, nor is there any evidence of inflammation. The nodules, however, appear in every instance on precisely similar points on opposite sides of the body, and the opposite lesions are always of uniform size and contour. I have been unable to make a diagnosis in this case, and the general appearance of the patient leads me to believe that unless some specific remedy is obtained the case will terminate fatally.

Is it a peculiar case of erythema nodosum, or some obscure nervous disease which manifests itself in this way? I would say, also, that there is no evidence of any abnormal condition in any of the vital organs.

A PAINLESS METHOD OF SKIN GRAFTING.

By CHARLES G. FOOTE, M.D.,
CLEVELAND, OHIO
ASSISTANT TO THE CHAIR OF SURGERY, CLEVELAND COLLEGE OF PHYSICIANS AND SURGEONS.

The operation of skin grafting, although exceedingly painful, hardly justifies the administration of a general anæsthetic. In the vast majority of cases nothing is done to obviate the pain of the operation, and consequently the suffering is intense.

The instruments for the painless operation required are: a sharp curette, a sharp razor, tissue forceps, and an ordinary hypodermic syringe and needle. Some Lister protective, oiled silk, cotton, gauze, sublimate solution 1 to 2,000, and alcohol are also essential.

If the wound is very recent, it is not necessary to curette. If, however, the surface is covered with granulations, the superficial ones should be removed with the curette; the slight pain connected with this part of the operation can be prevented by placing a piece of absorbent cotton saturated with a 4-per-cent. cocaine solution on the wound for about ten minutes.

A suitable place on the arm or thigh is prepared in an aseptic manner as for any ordinary operation, after which all antiseptics should be utterly discarded. An ordinary hypodermic syringe is filled with decinormal salt solution, the needle is inserted underneath the epidermis, and as much of the salt solution as possible injected into the skin, producing a wheal as in the ordinary Schleich infiltration method, although somewhat larger in diameter. It is very important that the injection be endermic, *i.e.* between the cutis vera and epidermis, and not hypodermic, otherwise the anæsthesia will be very imperfect. The needle is inserted three times in this manner, so as to produce an elevation or ridge about one and a quarter inches in length by one-half inch in width. The graft is then very easily removed by a sharp razor, without causing any pain. After

the wound has been well covered with grafts, it is protected by a reticulum of Lister protective, cut in strips, and then covered with sterile gauze moistened with salt solution. The gauze should be frequently removed, once or twice every day, and the wound gently irrigated with decinormal salt solution, leaving, of course, the Lister protective undisturbed until the grafts become firmly attached.

The advantages claimed for this method are (1) its painlessness, and (2) the removal of the grafts is rendered much easier.

THE OSBORN

A CASE OF TRIPLETS, COMPLICATED BY PARTIAL PLACENTA PRÆVIA AND TRANSVERSE PRESENTATIONS, FOLLOWED BY SEVERE POST-PARTUM HEMORRHAGE.

BY W. G. WILLIAMS, M.D.,
CROSS, TEXAS.

ON June 29th, at 8 P.M., I was called to attend Mrs. C. in her third confinement. This case had been under my care for some time and presented nothing more unusual than considerable œdema in the lower part of the abdomen, and of the lower limbs. The patient had complained very much of inability to get around, being fatigued on the least exertion. No examination was made before confinement, but from her general appearance multiple pregnancy was suspected. She was attended in her first two confinements by a midwife. The first of these was normal, the second being complicated by post-partum hemorrhage followed by fever of two weeks' duration. She menstruated last on August 25th, the date of her confinement being two hundred and eighty-seven days thereafter.

On examination, the os was found to be dilated about the size of a silver dollar. The membranes were unruptured and, on passing the finger into the internal os, I discovered that it was overlapped in its upper half by the placenta, which at this point was very thin, being scarcely one-quarter inch thick, and, as I afterward ascertained, was attached more to the left side of the uterus, not reaching the fundus by about five inches. The os was very tense, and throughout the labor uterine inertia was a serious complication. Hemorrhage at this time was very light, the os not having dilated sufficiently to tear many blood vessels. I decided to tampon, which I did, using 10-per-cent. iodoform gauze, first applying to the os a 5-per-cent. solution of cocaine hydrochlorate, containing one-half grain of atropine sulphate to the drachm. The tampon was allowed to remain three hours, five grains of quinine sulphate and twenty minims of fluid extract of ergot being given every two hours to stimulate pains. By this time the os was considerably dilated, and, the hemorrhage becoming severe, the placenta was peeled back several inches from around the os, and the head of the first fœtus, which was presenting by its right elbow with head in the right iliac region and back to the spinal column, was, by combined manipulations, brought down into the normal position. The os still not being sufficiently dilated for delivery, the vagina was again tightly tamponed to compress the bleeding vessels against the head of the fœtus and to facilitate dilatation. At this time I found myself in a dilemma often experienced by the country practitioner, *i. e.* I was without assistance. However, the woman was chloroformed, and the os having become sufficiently dilated, the membranes were ruptured and the first child, a six-pound boy, was delivered with forceps, the woman having then been in labor eleven hours. The pains improved after the first child was delivered, due, no doubt, to the fact that the uterus had previously been over-distended, each fœtus having its own amniotic sac, and, I should judge, each sac containing three to four pints of fluid. The position of the second child was corrected as soon as possible, it also being transverse. The hemorrhage continuing severe in the meantime, as soon as the head engaged the pelvis, the membranes were ruptured and the second child, also a boy, was delivered with forceps, twenty-five minutes after the first. This child presented by its left shoulder, but being small, no special difficulty was experienced in correcting its position. There was complete uterine inertia after the second child was delivered, and on account of hemorrhage it was found necessary to introduce the hand into the uterus and rupture the third bag of waters. Forceps was applied to the head of the third fœtus, and the child was rapidly delivered. I then had the grave responsibility attendent upon a severe post-partum hemorrhage. The uterus was whipped out and I could get no contraction, although ergot had been given every two hours until three teaspoonfuls had been taken. The placenta, which weighed five pounds and covered nine or ten inches of surface, was with great difficulty and much loss of blood detached and delivered. One quart of very hot water was then immediately thrown into the uterus, which caused some contraction, but not enough to arrest the hemorrhage. Strong vinegar thrown into the uterus was next tried, but the hemorrhage was only controlled after tightly tamponing and continually manipulating the uterus to keep up contractions. The woman at this time presented all the symptoms of impending fatal syncope, rapid thready pulse, shallow respiration, with severe nausea and cold extremities. Her head was immediately lowered, the foot of the bed was raised, and strychnine sulphate gr. $\frac{1}{30}$ was given hypodermically, while whiskey ℥ ss, was given internally. A saline solution, ℥ iv, to one-half gallon of water, was thrown into the rectum, which had been previously emptied. Under this treatment the patient gradually improved, small quantities of milk and whiskey being given every few hours, until the danger-point was passed, when the woman was put on iron, quinine, and strychnine. There was some rise of temperature a few hours after delivery, which gradually declined to normal, and under rigid aseptic treatment the woman made an uneventful recovery. Other items of interest in this case were that the three children were all males, and each fœtus had its own chorion and separate bag of waters. The first one delivered weighed six pounds, the other two five pounds each, all being well developed. The cords were separate and distinct, unusually large, and attached separately to the placenta. This latter was very large and its blood vessels were greatly developed, which would, in part, account for excessive hemorrhage. This placenta was examined carefully, and I am satisfied that it was single. The three children, at this time, one month after their birth, are doing well. At no time was albumin found in the woman's urine.

Size and Disease.—Properly speaking, giantism is a disease. Dr. Charles L. Dana of this city long ago gave out the opinion that many so-called giants were cases of excessive pathological development, rather than cases of excessive physiological growth. According to Professor Brissaud, giantism is nothing else than acromegalia. M. Brissaud has demonstrated that the combinations of giantism and acromegalia are far from being uncommon, and that the general symptoms of each one of these diseases are observed also in the other. According to M. Brissaud, acromegalia is the giantism of adults, while giantism is the acromegalia of adolescents

SECTION ON MEDICINE.

Stated Meeting, October 15, 1901.

JAMES N. WEST, M.D., CHAIRMAN *pro tem.*

Thrombosis of the Inferior Vena Cava.—Dr. O. HENSEL presented this case, a woman of twenty-four years, with a negative family history. There was no history of infectious disorder. Up to four years ago, according to her statements, she had not menstruated at all, but had vomited up blood at intervals. She is markedly neurotic. Three months ago the lower extremities became swollen and the veins prominent. There had never been any jaundice, there was no evidence of syphilis, and the result of mixed treatment had been negative. She had sought relief because of varicose ulcers of the leg. Examination had shown enlargement of the veins extending up on to the abdomen. Both the liver and spleen were enlarged. Throughout the four months she had been under his observation, there had been no change in her condition. The absence of ascites and of varicose hemorrhoidal veins and the distention of the abdominal veins afforded ground for a probable diagnosis of thrombosis of the inferior vena cava.

Dr. E. LIBMAN presented in this connection a specimen of thrombosis of the inferior vena cava. The specimen had been removed post mortem from a woman of thirty years, who had died of sepsis. There had never been any marked distention of the veins of the abdominal wall, but the legs had been swollen. One day she sat up in bed, gasped suddenly, and died instantly. The autopsy revealed thrombosis of the pulmonary artery. A thrombus also extended from the internal and external iliacs into the vena cava and up to the opening of the diaphragm. The veins of the legs could not be examined, hence it was a question where the thrombosis had begun. Streptococci in pure culture had been found in the thrombosis.

Dr. JAMES N. WEST said that he had been so unfortunate as to meet with two cases of embolism of the pulmonary artery. One of them had followed a simple gynecological operation, and had led to the death of the patient on the ninth day. The diagnosis had been confirmed by autopsy, but the origin of the process had not been traced.

Dr. LIBMAN said that he had examined the patient just presented by Dr. Hensel, and was inclined to agree with him in the diagnosis. From the history of vomiting of blood, it was possible that the condition had begun as a cirrhosis of the liver, and that this had been followed by phlebitis of the hepatic vein. It seemed to him most probable that the thrombosis of the vena cava was primary in this case.

Dr. HENSEL said that he had searched the literatures and had found a number of similar cases reported in which the etiology had been equally obscure.

The Influence of Electric Ozonization Upon Disease.

Dr. G. LENOX CURTIS presented a paper with this title. The machine used by him for this treatment is a high-frequency one, having a voltage of one million and an amperage of one-sixth. Owing to the low amperage there was no shock or unpleasant sensation produced. The machine has one pole; it is portable, and can be used at the bedside instead of the ordinary oxygen apparatus, provided an electric-lighting current is at hand. The patient remains in a cabinet for from twenty to thirty minutes to get the best results, and during this time inhales ozone and receives the high-frequency current. In addition, electric massage is given. The electric current is conducted to the patient through a vacuum glass electrode, and the patient is unconscious of the application of the electricity except through the sensation of warmth produced. The effect of the treatment on the blood was shown by an increase in the number of red corpuscles and an augmentation of the percentage of hæmoglobin, together with a diminution in the number of white corpuscles. The treatment was usually given daily, and ordinarily a good result would be manifest in the course of a month. The author said that he had used this treatment in about 250 cases, and had come to the conclusion that it was useful in both acute and chronic disorders. Among the diseases in which he had observed benefit from this treatment were tuberculosis, syphilis, carcinoma, locomotor ataxia, paralysis agitans, hysteria, meningitis, neurites, torticollis, paresis, nerve prostration, impotence, diabetes mellitus, Bright's disease, septicæmia, oophoritis, dysmenorrhœa, anæmia, and leukæmia. He had used it in a considerable number of cases of undoubted pulmonary tuberculosis associated with fever and bacteriological evidence of mixed infection. Two treatments had been given daily, and in each instance the sputa had become more liquid, the night sweats had diminished, and food, which had previously been rejected, was retained. After a week or two the pulse and respiration had improved, and there had been free expectoration of shreds of tissue and a very large number of bacilli. These cases were advanced ones, and had been treated only to observe the effect of the treatment, and not with any expectation of averting a fatal termination. Daily observations on the sputa of such patients under this treatment had proved to him beyond doubt that the ozone so influences the tubercle bacilli that they die quickly. The author stated that he had used the ozonic treatment in a few cases of external suppurative inflammation, and in two or three instances had obtained results little short of marvelous in cases of mastoiditis apparently calling for operation at the time. Very happy results had followed the use of electric ozonization in some cases of melancholia. He had treated ten cases of diabetes mellitus with very gratifying results. The quantity of sugar in the urine had varied from ½ to 4½ per cent. The effects of this treatment in alcoholism had been most brilliant, in both the acute and chronic cases. The pain, odor, and discharge had been diminished, as a rule, by electric ozonization in cases of cancer, and the general health had been very noticeably improved. This treatment had been employed in twenty-five cases of muscular rheumatism with complete success, even in severe cases of long standing. In rheumatoid arthritis the results had been equally good, though obtained much more slowly.

High Potential Electric Modalities in the Treatment of Diathetic Diseases and Inflammatory Conditions.—Dr. WILLIAM BENHAM SNOW was the author of this paper. He said that the voltage of a static machine was dependent upon the size of the plates and the amperage upon their number. The static machine for electrotherapeutic work should be constructed according to the most modern and approved plans, and have eight glass plates, thirty inches in diameter. They should be actuated by a motor capable of imparting to the machine a speed of 300 or 400 revolutions per minute. It was also desirable that there should be at hand means for gradually increasing and diminishing the speed. The mode of treatment most commonly employed at the present time was that in which the high-frequency current is administered by means of one pole. General diaphoresis was produced in most patients subjected to the wave-current for upward of thirty minutes. There was also a marked increase in the total quantity of urinary solids eliminated. Nothing interferes so much with the relief of pain and inflammation, in connection with such a treatment, than a thick layer of adipose tissue under the skin. Among the local effects of the current were: (1) Stasis; (2) The absorption of any inflammatory exudate present and not

too deeply situated; (3) The induction of a healthy metabolism; (4) A prolonged lowering of arterial tension after the application of the wave-current; (5) A marked rubefacient effect after a prolonged application of the brush discharge. In order to produce constitutional effects the séance should last for thirty minutes, and the treatment should be repeated daily for at least two weeks, and then given on alternate days. The electrode should have an area of from fifteen to twenty-four inches, and the spark-gap should be four to eight inches long.

Dr. G. Lenox Curtis then demonstrated his apparatus, showing the potency of the high-frequency current and its extended sphere of action. The machine itself consists of a series of step-up coils.

Dr. A. D. Rockwell said that while he had been impressed with the earnestness of the authors, he did not feel quite certain that the remarkable therapeutic results reported could be generally obtained by others. He could, however, easily understand the good effect of saturating the system with ozone generated by electricity. His own experience had been that these high-frequency currents were not beneficial in tubercular conditions, and that they sometimes even did harm in such cases. Neither was he prepared to admit that they are useful in the treatment of acute inflammatory conditions. For the removal of plastic deposits due to inflammation, he thought we must rely upon the galvanic current, but for increasing circulatory conditions and improving nutrition, the high-frequency currents were exceedingly valuable. These currents cause, first, a lower blood pressure, and then, a higher blood pressure and an increased vascularization. For this reason these currents must be as applicable to the treatment of hyperæmia of the kidney as for the relief of joint affections, and his own experience had confirmed this view.

Dr. William James Morton said that he had nothing but unbounded praise for the character of the work forming the basis of these two papers, as well as for the courage of these men in coming forward and frankly giving their results. These results, remarkable as they might seem to many, were but the echo of an old story in his ears; they were perfectly attainable by any one who will make a proper application of these high-tension currents. He had made many experiments at one time with ozone, and they had led him to the belief that ozone does not penetrate the body, and has no place in the treatment of disease. He would, therefore, explain the excellent results obtained not by the action of the ozone, but by the effect of the high-tension electric current. Such a current affects profoundly every particle of protoplasm, and this, in itself, was a sufficient reply to the scoffing critic who points skeptically to the claims of electrotherapeutists that electricity is beneficial in such a great variety of diseased states. A most encouraging sign of the times was the tendency to carry electrotherapy into the field of acute diseases. He could personally bear testimony to the truth of all of Dr. Snow's statements concerning the electric treatment of acute inflammatory conditions. The high-tension current not only causes rapid absorption, but it does this much more quickly than the galvanic current, and at the same time relieves the pain.

Dr. Robert Newman said that, as a victim of inherited gout and a sufferer from acute rheumatism, he was in a position to bear personal testimony to the value of the high-tension current in the treatment of acute inflammation. Only recently he had had a severe attack of acute rheumatism in one knee, and had been both astonished and delighted at the way in which Dr. Snow, by electrical treatment, had reduced the swelling and caused the pain to vanish. The electrical application had been made to his painful and swollen knee in the form of the electric breeze, using Dr. Snow's soft-wood electrode moistened with water. Dr. Curtis's method of electric ozonization seemed to him decidedly original, and the current employed by him had certainly been demonstrated to have great potency.

Dr. Mary Putnam Jacobi coincided in the view expressed by Dr. Morton, that ozone had not been demonstrated to have any share in the effects described by Dr. Curtis. These results could all be explained by the action of the high potential current.

Dr. O. D. F. Robertson gave his personal experience with the treatment, and declared it to be his belief that his recovery from a slowly resolving pneumonia had been effected by this treatment advocated by Dr. Curtis, and that a large share of the credit was due to the ozone. The opinion was founded not only on the fact that it had had a marked effect on the expectoration, but because it was in line with the generally accepted views regarding the high value of fresh air in the treatment of respiratory diseases, especially pulmonary tuberculosis.

Dr. Margaret A. Cleaves said that she, too, questioned whether the ozone had had anything to do with the cure of the cancer in the case reported, though the favorable influence exerted on cough and expectoration in pulmonary cases could probably be explained in this way. As the high-tension current was very rich in the ultra-violet rays, she was disposed to hold these rays, more than the ozone, responsible for the good result in the case of cancer.

Dr. John B. Rich said that, after having suffered for about nine years from lupus of the nose, and receiving no benefit from the usual methods of treatment, he had placed himself in Dr. Curtis's hands, and, as those present could verify for themselves, the improvement in his condition had been both rapid and most satisfactory.

Dr. Snow thought that in the cancer case the good result had been effected by local oxidation.

Dr. Curtis, in reply to questions from the chairman, said that the case of cancer to which reference had been made was one involving the breast. Seven operations had already been done, and the breast was at the time a large, foul, ulcerating mass. The odor had almost immediately disappeared, and within three weeks the disease had entirely disappeared. In the case of diabetes mellitus, the diet had not been in any way changed, and no other treatment than electric ozonization had been employed. Dr. Curtis then exhibited the case of torticollis that he had reported in his paper as having been so greatly improved.

NEW YORK ACADEMY OF MEDICINE.

SECTION OF SURGERY.

Stated Meeting, October 14, 1901.

John B. Walker, M.D., Chairman.

Trephining for Traumatic Epilepsy.—Dr. Charles H. Peck presented a young man whose skull he had trephined to relieve a traumatic epilepsy. A bullet had been found imbedded in the outer table of the skull, but not affecting the inner table. Recovery had been uneventful, and he had been up and around in a few days. The wound had been entirely healed after four weeks. No convulsions had followed the operation until a week ago, or nine weeks afterward, and then the seizure had been a mild one.

Fractures of Both Forearms.—Dr. Carl Beck presented a laborer who had received a severe crush, resulting in fracture of the radius and ulna in each forearm. He had been treated in a hospital for three months, but on leaving there had had paralysis and loss of sensation in the affected parts. He had then come under Dr. Beck's care. The first Röntgen-ray picture had shown a considerable overlapping of the fragments on both sides. On August 4, he had cut down upon the parts, overcome the overlapping, and fastened the fragments with silver wire. The parts had been easily and fully exposed by means of a semilunar incision. The case was not presented to show a good result, but the difficulties

and the assistance rendered by the Röntgen rays in showing surgeons their errors.

Removal of Fractured External Condyle of the Humerus.—Dr. Beck also presented a boy of five years who had fallen from the second story of a house. After the case had been treated for some time in a hospital, it had come to him. Examination showed an inability to bend the arm and a small fragment of bone on a level with the lower end of the humerus. Under the guidance of the Röntgen rays, this piece of bone, the external condyle, had been removed, and immediately thereafter the arm could be bent, although this had been impossible previously. The case was now doing well.

Skiagraph of Traumatic Lung Abscess.—Dr. Beck presented a young man, a rough rider, who had been stabbed in the back during the Spanish-American War. He had been treated in the Montclair Hospital and Dr. Newton had informed him that an operation for resection of rib had been done there.

Fracture of the Anatomical Neck of the Humerus.—A boy was also shown who had sustained a fracture of the anatomical neck of the humerus. The case had been successfully treated by a new principle, viz. upward lifting of the whole arm.

Fractures of the Lower End of the Radius.—Dr. Beck said that it was generally considered that the typical displacement of Colles' fracture was the "silver-fork" displacement. A skiagraph of a typical case of this fracture was exhibited showing not a dorsal, but a lateral displacement. The force had not been great enough to fracture the ulna, the boy being young and the bone soft. A skiagraph was then shown of an old lady with this fracture. It had presented no outer deformity at the time of injury, only an inability to bend the hand. Every attempt at passive motion had been followed by pain and great swelling, and finally the lady had refused to allow her physician to continue the treatment. A Röntgen-ray picture had revealed a displacement of the ulna with a ragged edge of bone. The parts should either be laid to rest and thus secure ankylosis, or, if a better functional result were aimed at, the irregular piece of bone should be chiseled off. Another boy was shown with fracture of the lower end of the radius. The diagnosis had been made by the great pain and the false point of motion, although crepitus had been absent. The first skiagraph taken of this case had failed to show any evidence of a fracture, but being sure of the existence of a fracture, a second skiagraph had been taken from the side, and in this the fracture had been made very evident.

An Improvised Urethral Sound.—Dr. A. V. Moschcowitz presented a man, twenty-eight years of age, a tailor by occupation. At birth it had been found that the urine was voided from an orifice on the inferior surface of the urethra. He had been operated upon at St. Luke's Hospital for hypospadias, and after a number of operations this condition had been cured with the exception of a small opening at the base of the glans penis. Nine years ago he had had gonorrhœa, and this had lasted for three years. About twelve weeks ago, during the absence of his physician, it had become necessary to pass a sound, and the patient had improvised one out of a bone pen-holder. Very naturally, the instrument had slipped from his grasp and had passed into the bladder. Dr. Moschcowitz removed it by suprapubic cystotomy.

Trephining for Epilepsy; Healing by Blood Clot.—Dr. Robert T. Morris presented a boy who had sustained a depressed fracture of the skull three years ago, and had been operated upon at the time by some surgeon. The wound had suppurated, and an abscess had formed. The boy had subsequently developed convulsive seizures, apparently dependent upon reflex irritation from the scar. Dr. Morris said that he had chiseled out the entire area of the scar, and in doing so had found it necessary to remove a considerable portion of brain tissue. The wound being very deep, it had seemed to him that there would be great difficulty in adjusting either gutta percha or foil, hence he had allowed the wound to fill with blood clot in the hope of securing a soft scar. The day following the operation there had been marked hemiplegia, but he had pretty well recovered from this. There had been two epileptic seizures before the operation, but none since then. This, of course, did not necessarily possess any great significance.

Dr. S. Lloyd said that he had had considerable experience with fractures at the elbow joint, and this had taught him that it was better to resect a portion than to attempt to replace it. After the union had been fairly complete, it had been almost impossible to chisel the small fragment away and secure a permanently good result. Another difficulty had been the increased amount of callus thrown out after operations for replacing fragments. A partial resection of the joint causes less discomfort and gives a better result. For this reason he could only commend the method pursued by Dr. Beck.

Dr. A. Ernest Gallant said that in a case of fracture of the inner condyle he had tried the experiment of keeping the arm moving all the time, and subjecting it to massage. At the end of a week, the arm could be used well, and the man had been able to go to work after three weeks. Motion had then been limited by the callus. He had hoped by this treatment to prevent the formation of this callus. This was the first case of the kind that he had treated without immobilization.

Dr. R. T. Morris said that last winter he had used in two cases of abscess of the lung Murphy's method of injecting nitrogen into the pleural cavity under pressure. It had seemed to him to assist the healing.

Foreign Body in the Bladder.—Dr. John A. Hartwell presented a foreign body removed from the bladder of a woman in the Colored Hospital. She had been admitted to the hospital for an inguinal adenitis, and while being prepared for operation it had been noted that the urine was very foul. This had led him to examine the bladder, with the result that he had discovered a stone. Through a suprapubic incision he had exposed a large calculus attached to a metal catheter. He had learned subsequently that the catheter had been there for two years. A rubber catheter was inserted, according to Dr. Gibson's method, and the bladder had been kept open for drainage from the time of the operation on July 6 until August 2. She had left the hospital on August 10. Under close questioning, the woman stated that two years or more ago she had had a miscarriage, and that it had become necessary to catheterize her. The physician who did this in some way lost the catheter in the bladder. He at once told her that an operation for its removal was necessary, but she would not consent to this.

Practical Results in One Thousand Cases of Nitrous-Oxide and Ether Narcosis.—Dr. H. W. Carter read a paper with this title. He said it was of the greatest importance in administering nitrous oxide to keep close watch upon the respiration, and to admit air on the first sign of suffocation. Certain individuals, particularly women and children, could be easily asphyxiated with a small quantity of this gas, even the small quantity used preparatory to other narcosis. Plethoric and alcoholic patients, on the other hand, often require considerably more than the average quantity of gas. He seldom found it necessary to allow more than a slight degree of cyanosis to develop in these cases. Respiration is almost always interrupted if ether is turned on before unconsciousness supervenes. In cigarette-smokers, or others, having hyperæsthesia of the larynx, it was often necessary to proceed with the greatest caution. In the first and second stages of narcosis, the heart beats quietly, fully, and regularly, but as the anæsthesia grows more profound, and the respiration becomes stertorous, the pulse becomes small, hard, and slightly accelerated. The blood

pressure is somewhat lowered, chiefly due to dilatation of the superficial capillaries. During profound anæsthesia, the renal vessels are contracted, and the secretion of urine diminished. The main advantages of nitrous oxide, as a preliminary to ether, were its almost perfect safety and its rapid and pleasant action. By using first nitrous oxide-gas and then ether, full surgical narcosis is secured almost immediately, and can be maintained with a very small quantity of each of these agents. Upon the respiratory center, ether acts as a powerful stimulant, but if carried too far it arrests respiration by paralyzing the respiratory center. It also powerfully stimulates the heart, and, unlike chloroform, when the heart begins to fail, it does so slowly, and gives ample warning. Vasomotor shock and reflex inhibition of the heart's action constitute an element of great danger at all times under incomplete chloroform anæsthesia. While ether is an irritant to the kidneys, it exerts but little effect on these organs if they are healthy and the ether is administered skilfully. Water should be given freely, both before and after etherization, unless it causes nausea and vomiting. Nephritis following the administration of ether is, in the author's opinion, more often due to exposure during the operation, or to the unskilful use of the anæsthetic than to the inherent effect of the ether. In view of the fact that chloroform is a powerful protoplasm poison, and in equal quantity far more irritating to the kidneys than the ether, it seemed to him not improbable that if the necessary quantity of ether could be reduced nearly to that required in the case of chloroform, it would be better than the latter in cases of albuminuria and nephritis to use ether rather than chloroform. In valvular disease of the heart, provided there is good compensation, nitrous oxide and ether can be administered with perfect safety. Old people take gas and ether particularly well, but special care should be exercised in such cases, and its use should be avoided in all cases of arterial degeneration.

An Adjustable Automatic Mouth Gag.—Dr. CARTER then exhibited this gag, which had been primarily designed by him to aid the anæsthetist in cases in which there was some mechanical obstruction to respiration. With the mouth gags commonly in use, it was very difficult properly to apply the face mask. To obviate these difficulties, he had devised a gag which, while in use, would lie perfectly flat against the cheeks. In order that the instrument could be adjusted to the individual face, a hinge joint is used, and to secure the requisite rigidity, a cogwheel and lever are so arranged that they form an automatic catch. As each side of the instrument is independent of the other, it is easy to adjust it to any irregularities in the mouth. He thought the instrument would prove very useful to dentists, and also in operations for the removal of the tonsils.

Dr. W. B. DE GARMO said that the reader of the paper had administered the gas and ether for him over two hundred times. Among these cases there had been a number of very bad subjects, not only because of their general build, but because of the existence of various heart lesions. There could be no doubt that the after-effects were nothing like so severe as after ether alone. This was to be expected, because of the comparatively small quantity of ether employed by the combined method. So far as he had observed these cases there had been absolute freedom from complications.

Dr. EUGENE FULLER said that he had seen one patient badly asphyxiated from the use of nitrous oxide-gas in the hands of an unskilful anæsthetist. In that case the prolonged use of artificial respiration had been required in order to resuscitate the person. In cases of operation upon an infected genito-urinary tract, it was probable that suppression of urine was likely to occur with any form of anæsthesia. He was not afraid with ether in such cases, provided the patient was not overwhelmed with the anæsthetic by the anæsthetizer. The speaker referred to a case which he had seen in which the administration of chloroform had resulted in the complete failure of respiration five to ten minutes before the cessation of the heart's action.

Dr. S. LLOYD said that he was very glad that at last in this country the importance of having skilled anæsthetists was recognized. Eighteen years ago he had written a paper on the effect of ether on the kidneys, and that paper had been suggested by seeing a series of cases in which nephritis had been apparently induced by ether anæsthesia. The reader of the paper this evening had struck the keynote of the question when he had said that the effect of ether on the kidneys depended very largely upon the mode of administering it. At one time he had been of the opinion that ether was better than chloroform in cases of disease of the kidney. Subsequent clinical experience had shown him, however, that irritation of the kidneys was not uncommon after the administration of chloroform by the junior members of the hospital house-staff. By slight irritation he did not necessarily mean that albuminuria developed, but that the urine contained casts of various kinds. Dr. Lloyd said that for many years he had made it a custom to precede anæsthesia by the administration of $\frac{1}{4}$ gr. of morphine and $\frac{1}{100}$ gr. of atropine, and in cases of bronchorrhœa it was his rule to give an additional dose

Dr. A. ERNEST GALLANT said that the position of the head had much to do with the development of excessive secretion in the throat. The trouble was that the pillow was often put under the shoulders, and the head allowed to fall back. By a careful adjustment of the position of the head on the pillow in each case one was able to avoid much of this trouble from secretion in the throat, and at the same time reduce the quantity of ether administered. He recalled one case in which, while giving ether, the heart's action had suddenly ceased while the respiration had continued, and vigorous efforts at resuscitation had been demanded. The speaker said that he had used nitrous-oxide gas a good deal for the past seven or eight years, but he would say that he felt sure that he could, in the average case, anæsthetize with as small a quantity of ether alone as most anæsthetists use in connection with nitrous oxide. One great objection to the combined gas-and-ether method was the necessity for using a complicated and expensive apparatus. This was a decided disadvantage in country districts, particularly under our unfortunate system of turning out graduates in medicine and sending them out over all the country without any practical instruction in the administration of anæsthetics.

Dr. CARTER, in closing the discussion, said that his experience had been that the nitrous-oxide cyanosis clears up almost immediately after the patient has fully come under the influence of the anæsthetic, and a sufficient quantity of air can be admitted. During the remainder of the administration the patient is not only free from cyanosis, but often has a heightened color. He did not think the nitrous oxide tended to increase the bronchial secretions. Occasionally, one met with cases in which the bronchial secretion is so troublesome that it seems advisable to change to chloroform. His experience had been that there is almost always a diminished secretion of urine in the first twenty-four hours after anæsthesia; but this he believed was dependent upon diminished ingestion of fluid, increased diaphoresis, and perhaps other factors not directly connected with the anæsthetic.

An Island for Lepers in the Philippines.—The *Army and Navy Register* states that the island of Barri, to the north of Luzon, has been recommended for the segregation of Philippine lepers. The board of officers appointed to investigate the matter reported as follows: The island is uninhabited, is two miles long by one wide, near Luzon, and is suitable so far as water supply, climate, etc., are concerned. Its disadvantages are its nearness to the island of Fuga and the frequency of typhoons.

NEW YORK COUNTY MEDICAL ASSOCIATION

Stated Meeting, October 21 1901

PARKER SYMS, M.D., PRESIDENT.

A New Percussion Mallet.—Dr. HEINRICH STERN, in presenting this new instrument, said that a percussion hammer should be permanently attached to the plexi-meter, and the strokes should be uniform in force and duration. The action of the instrument reminded one of the spring mallet used by dentists. To its distal end is attached a disk, which serves as a plexi-meter. The use of the instrument on a patient was demonstrated.

A Retractor for Use in Prostatectomy.—Dr. J. W. S. GOULEY presented an instrument for use as a retractor during the enucleation of the diseased prostate. It was intended to take the place of the finger. It is introduced into the urethra through the perineal cut, the parts having been sufficiently dilated to admit the index finger. The instrument is introduced with the point of the beak looking upward, and on reaching the bladder it is reversed. It is then out of the way of the operator.

Fibroid Tumor of the Fallopian Tube.—Dr. J. RIDDLE GOFFE presented this specimen. The tumor had been located about three-fourths of an inch from the horn of the uterus on the left tube, and although not occluding the latter, had completely surrounded it. Jacobs of Brussels had reported one similar case, the first one in his experience. This was the only other case that Dr. Goffe had found recorded. The tumor had been taken from a young woman who had suffered all her life from dysmenorrhœa, and who had been an invalid for four years previous to coming under his observation. He had operated to restore the displaced uterus, doing the operation through the anterior fornix of the vagina. On the opposite tube was a cyst of Morgagni. The fimbriated extremity of this tube was open sufficiently to admit the thumb, and the cyst protruded from this opening. Both ovaries and the right Fallopian tube had been allowed to remain.

Dr. A. PALMER DUDLEY said that he had seen but one case of fibroid tumor of the Fallopian tube in an experience of twenty-seven years, nor had he been able to find any other case on record than the one alluded to by Dr. Goffe. It seemed to him probable that the same conditions which produce fibromas in the fundus of the uterus should give rise to a fibroma of the tube itself, although probably many would not be willing to accept this suggestion. The history of the case reported seemed to point to a chronic congestion of the structure of the tube, and this would be favorable to the development of a fibroid. These cases were just as apt to occur in the young woman as in one near the menopause.

Dr. FREDERICK HOLME WIGGIN said the rarity of such cases was evident from the fact that he had not met with a single one in a rather large experience.

Dr. A. BROTHERS said that he, too, had not met with a fibroid of the tube. He had, however, met with two cases of fibroid of the ovary. One of these tumors had been as large as a cocoanut.

Spasmodic Affections of the Larynx.—Dr. EMIL MAYER read a paper on this subject. He said that among children spasm of the larynx was not of rare occurrence, and it might occur in the adult. Several cases were on record in which laryngeal spasm had existed in the newly born infant. In one of these cases it had been evident that the spasm had been excited by an embryonic state of the epiglottis. Rickets stood at the head of the list of etiological factors, but dentition, large and caseous glands, inflammation of the air passages, digestive disturbances, and the presence of an excessive quantity of lymphoid tissue were other common causes. The suddenness of onset, absence of increased temperature, and the results of bacteriological examination made the differential diagnosis from diphtheria not very difficult. Unless the attack were due to direct cerebral irritation the prognosis was good. Death might occur either from asphyxia, suffocation, cardiac exhaustion, or cerebral compression might arise from transudation between the cerebral membrane and the vessels. The treatment should consist in rest, regulation of the diet, the ingestion of small quantities of food at a time, and the keeping of the child outdoors in good weather. Chloral and the bromides were useful in the treatment of the attack. Laryngeal spasm in the adult was much less frequent than in children. It might occur in hysteria, chorea, and epilepsy, and in connection with tetanus, hydrophobia, and tabes. It had been noted as an extremely early symptom of tuberculosis. The spasm might be of three kinds, *i.e.* of phonation, deglutition, and respiration. The differential diagnosis was readily made with the laryngoscope. A most interesting form of spasm was that known as laryngeal vertigo, or laryngeal epilepsy. Asthma and excessive smoking, combined with hypertrophy of the nasal mucosa, elongation of the uvula, hypertrophy of the lingual tonsil, tabes, and bulbar paralysis were among the causes. Almost all of the cases reported had occurred in males between forty and forty-five years of age. The attack is caused by some irritation of the superior laryngeal nerve. It simulates an epileptic attack; but there are few, if any, muscular spasms, the tongue is not bitten, there is no involuntary defecation, and no headache. Few maladies to which flesh is heir cause so much unhappiness as stammering. The speaker looked upon stuttering as a prodrome of stammering. Stammering is the incoördination of the three mechanisms of speech, *i.e.* the respiratory, the vocal, and the aural. In the medulla oblongata lay the nerve-center concerned—the basal phonic center. Fully 95 per cent. of stammerers are males, though the reason for this has never been explained. Under proper care, physiological voice-sounds should be persistently taught, the extrinsic muscles brought into proper play, and their psychological as well as physiological action brought into use. No force should be used, but gentle and persistent efforts, and with these a cure could be effected in the majority of cases.

Dr. FRANCIS J. QUINLAN thought from 75 to 85 per cent. of the spasmodic affections of the air passages occur in children. It was known that catarrhal disturbances play a very important part in their causation. He did not think that intestinal irritation played as important a part in the etiology as the textbooks would have us believe. In all cases of laryngeal spasm the effort should be made to discover any abnormalities in the air passages, such as accumulations of lymphoid tissue, or the presence of greatly hypertrophied tonsils. The lymphoid tissue at the base of the tongue created no end of trouble, and often gave rise to glottic spasm. The most important thing to remember in connection with these affections was the need for treating the upper air passages.

Dr. WILLIAM M. LESZYNSKY said that spasmodic affections of the larynx were common in chorea, hysteria epilepsy, and locomotor ataxia. The type seen by the neurologist was usually due to some form of irritation of the pneumogastric nerve, or the recurrent laryngeal branch. Reflex spasm was always bilateral. Spasm of the glotti in children was closely related to tetany, a condition intimately associated with rachitis. A subcutaneous injection of apomorphine generally proved successful in relieving the spasm. In patients suffering from chorea, there was often a barking cough which had sometimes been incorrectly described as chorea of the larynx. The initial cough, which often ushers in an epileptic attack, was due to momentary spasm of the larynx. Laryngeal vertigo was a very rare condition. It was a reflex neurosis, and had a good prognosis. A small percentage of patients suffering from tabes suffer from laryngeal crises. The paroxysms vary greatly in character, and may resemble whooping-cough or laryn-

gismus stridulus. He had seen two cases of tabes in which the diagnosis had been whooping-cough because of the existence of this paroxysmal cough. Death had occurred from such spasm, but was extremely rare from this cause. He could not agree with the reader of the paper in classifying stammering as an affection *per se* of the larynx. As a rule, it should be looked upon as merely a form of incoördination, and its cure is entirely dependent upon suitable and persistent systematic training.

Dr. J. H. WOODWARD said that it was only in children that one meets with that peculiar affection known as laryngismus stridulus. It occurs especially in rachitis, and the treatment should not be by bromides, but by supporting measures and improved hygiene. In the adult, laryngeal spasm occurred from reflex disturbance, the result of hyperæsthesia.

Dr. CHARLES E. QUIMBY said that some had considered the nocturnal spasm occurring in persons who had been drinking to excess as a spasmodic affection of the larynx, but he was inclined to look upon it as dependent upon an exhausted condition of the heart.

Dr. A. D. WAY of Wyoming County said that on two occasions when he had been called upon at night to treat a case of croup, and had not happened to have the usual remedies with him, he had injected nitroglycerin and with good result.

Dr. D. S. DOUGHERTY said that he had been collecting statistics as to the existence of adenoids in children subject to croup, and had been astounded at the very large percentage of croupy children in whom accumulations of pharyngeal adenoids had been found. He cited a case in which a very severe spasmodic laryngitis had occurred in a young girl. It had already passed through the hands of two specialists before coming to him. After thorough cocainization of the larynx, he had succeeded in examining the larynx with the laryngoscope, and had discovered a medal wedged in tightly between the arytenoids and the epiglottis.

Dr. M. E. VARNEY of Saratoga Springs said that he had observed marked relief following the administration of nitroglycerin in spasmodic laryngitis.

Dr. FRANK A. BRYANT said that he could not look upon stammering as a laryngeal affection solely, because he had seen it associated with spasms in other parts of the body.

Dr. HENRY W. BERG said that he had used bromide of potassium as he would in epilepsy in cases of laryngismus stridulus, and had been delighted to observe its marked controlling influence.

Dr. MAYER said that he had also found bromide of potassium exceedingly useful in this class of cases. He did not wish to be understood as considering stammering an affection of the larynx alone; it was merely an interesting neurosis to study in connection with the subject under discussion.

Report of the Committee on Vaccination.—Dr. FREDERIC W. LOUGHRAN, chairman of this committee, presented the report. It declared that the State of New York was almost the only State in which vaccination could not be enforced during an epidemic of smallpox. The following were the principal recommendations of the committee: All boards of health of cities and towns should furnish the means for vaccination and revaccination, and the State Board of Health should have authority to enforce vaccination during the prevalence of an epidemic of smallpox. No child should be admitted to any school who has not been vaccinated within a period of five years. Inmates of State asylums should be vaccinated on entrance, and members of the National Guard should be required to be vaccinated. All corporations or firms employing more than ten persons should be compelled to employ only persons who had been successfully vaccinated, or who presented a certificate from a reputable physician stating that they had been twice vaccinated, and that vaccinal insusceptibility exists. The penalty for violation of such laws regarding vaccination should be a fine of from $50 to $100, or an equivalent term of imprisonment, this penalty not to stand in lieu of vaccination.

The report was received, and the committee requested to continue its labors and to confer with the Committee on Public Health.

Surgical Suggestions.

Observations in Intra-Nasal Operations.—Charles M. Robertson (*Medical Age*, August 25, 1901) concludes: (1) The utter uselessness of treating a growth of organized tissue in the nostril by the application of sprays and the galvanocautery. (2) Where such growths exist, treat as you would an overgrowth elsewhere. (3) Save all the venous sinus tissue possible and still secure breathing space enough. (4) The advantage of the suprarenal capsule in nasal surgery. (5) The absence of danger of synechiæ forming, as they often do, after the use of the galvanocautery or caustic. (6) The use of dry pledgets of cotton and the disuse of all fluids. (7) The great advantage of the greased gauze as a surgical dressing in the nose over old methods. (8) The danger in the use of cocaine lessened by the use of the suprarenal capsule extract. (9) The disappearance of nasopharyngitis after the nose becomes ventilated.

Treatment of Cervical Adenitis.—(1) The cause of tuberculous adenitis of the cervical region is almost always local, and takes place through the buccal cavity. (2) The glandular manifestation, when it progresses, and especially when it is followed by suppuration, indicates a damaged and usually useless, often dangerous, gland. (3) The removal of such a gland *in toto* and promptly is neither difficult nor dangerous, and is the treatment indicated. (4) Nature will probably provide a new and equally perfect protection in the place of the one that is lost. (5) Multiple enlarged glands indicate a constitutional tendency which will not be benefited by removal, except when local discomforts and dangers indicate it. (6) Small groups or single slowly growing glands are subject to the same indication.—*H. H. Grant.*

Treatment of Sprains.—Van H. Coles (*Southern Practitioner*, September, 1901) says: If a case is seen immediately, that is in the first hour or two, it should be plunged into very hot or very cold water and there allowed to remain about thirty minutes, or until the blood vessels have thoroughly contracted, and by this first treatment we prevent much of the swelling, effusion, and inflammation. Then, the limb should be elevated and bandaged from below upward, and after twenty-four hours a plaster-of-Paris or other snug and immovable dressing should be applied, but renewed as the swelling subsides. At the end of two or three weeks, passive movement of the joint should be begun, but the direction of the movement is important, so as not to interfere with the strained and ruptured ligaments. After the removal of the plaster-of-Paris bandage, a leather support with lateral hinges, so as to allow flexion and extension and yet control any lateral or abnormal movement, is of great service. I will state, just here, that in cases of much laceration great care should be had that the joint is not used too early, as this is often responsible for the permanent weakness.

Surgical Hints.—The ether of chloride-of-ethyl spray will sometimes prove quite useful in stopping severe bleeding from cancerous or other ulcerations in which the hemorrhage is rather of an interstitial than an arterial character.

Never give an emetic, in order to recover a foreign body that has passed into the stomach. If it is small enough, it will always be passed in the course of a few days, while, if too large for this, vomiting would be a dangerous and useless thing to bring about.

An attack of hysteria simulating unconsciousness in a woman may be aborted by the surgeon taking up a pair of scissors and regretfully announcing that he will have to cut all the patient's hair off, in order to make applications to her head. It is doubtful whether this bluff has ever been known to fail.

When feeling for fluctuation in any part of the body that is covered by heavy muscular structures, place the hands along the long axis of the muscular fibers, and never across them. The latter position would certainly deceive the observer into thinking that fluctuation is present, as may easily be seen in the case of the large anterior muscles of the thigh.

In furuncles and carbuncles of the upper lip it is especially important to operate promptly, usually by thorough excision under an anæsthetic. The location of the disease, in such cases, makes them peculiarly dangerous, owing to the possibility of the occurrence of rapid thrombosis of the facial veins, extending to the cerebral sinuses. This, in turn, is apt to cause fatal pyæmia.—*International Journal of Surgery*, July 1, 1901.

Surgical Suggestions.—Sprains are treated satisfactorily and are rapidly cured by massage with a roller connected so as to furnish static electricity.

In incised wounds about the angles of the eyes and the mouth it is often better to use adhesive plaster instead of stitching; the constant motion is apt to irritate the parts or tear out the stitches.

It is good practice in all surgical cases to eliminate bacterial and metabolic products by increasing the secretion and excretion of the kidneys, intestines, and skin.

When the steam bath is indicated in country practice, it is easily and satisfactorily given by boiling a dozen or more ears of corn, taking them from the water while boiling, wrapping in cloths moistened in hot water, and packing them as close to the patient as possible. Keep him closely covered, and a few moments will bring the most profuse perspiration you ever saw.

Under certain conditions and in certain localities, pus sinuses and fistulas may be healed by thorough antiseptic washing, followed by packing the sinus with good drainage material, and binding the parts so that the walls of the sinus are held in close apposition. The gauze is shortened from time to time as the granulations coalesce behind. This method is most suitably applicable to recent cases, but is occasionally successful in even inveterate cases.

In tetanus of quick incubation, with known lesion, the antitoxin treatment yields the best results; in cases of unknown incubation, without discoverable lesion, the antispasmodic treatment is best.

Both the A, C, E, and the Schleich mixture are dangerous anæsthetics in the hands of those without extended experience. It is better for the ordinary practitioner to stick to his old favorites until some more certain knowledge is obtained regarding the limitations of the newer anæsthetics.

In case of a severely bleeding vessel, do not waste too much time in trying to ligate. Compress with fingers, packing, bandage, or tourniquet till assistance arrives. It matters not whether the vessel be vein or artery.

In the selection of a styptic, use only one which will hasten or assist the natural process of healing. Alum is the least objectionable of the chemical astringents: it may be applied in warm solution on any kind of aseptic compress. As it cools under pressure, it deposits aseptic crystals about the vascular orifices.—*Auburn Clinic*, September, 1901.

Medical Items.

Contagious Diseases Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week ending November 2, 1901:

	Cases	Deaths
Measles	152	4
Diphtheria and croup	226	29
Scarlet fever	153	6
Smallpox	5	4
Chickenpox	17	..
Tuberculosis	245	134
Typhoid fever	57	20
Cerebrospinal meningitis	..	4

National Types Changing.—*Chambers's Journal*, a British periodical especially given to dealing with matters of curious interest, has in a recent issue an article bearing upon the fact that the physiognomy of highly civilized races has been and is undergoing a change. The writer of the contribution in question first treats of the undoubted alteration in physique and appearance of the British, French, and Germans, giving his views as to the cause thereof, and then goes on to say: "But, perhaps, the most extraordinary metamorphosis of all is taking place under our eyes among two nations as widely separated in origin and history as it is possible for any civilized countries to be—America and Japan. The American physiognomy is as completely marked as that of any race under the sun, as Anthony Trollope remarked, bred in and in for centuries.' Yet, as the same traveler pointed out, the American owns a more mixed blood than any other race known. His chief stock is English, and with this are mixed the bloods of Ireland, Holland, France, Germany, Scandinavia, Italy, and Slavonic Austria. 'All this has been done within a few years, so that the American may be said to have no claim to any national type of face. Nevertheless, no man has a type of face so clearly national as the American. The lantern jaws, the thin, lithe body, the dry face, the thick hair and thin lips, the intelligent eyes, the voice not altogether harsh, though sharp and nasal. All these traits are acknowledged all over the Continent of Europe. Yet, perhaps, Trollope was mistaken in attributing the formation of this type to 'hot-air pipes and dollar worship,' although not altogether wrong in supposing the American countenance to be modified by his 'special aspirations.'"

Illiterate Immigrants.—The percentage of illiteracy, says the New York *Tribune*, October 27, is increasing yearly, according to the report of the Commissioner of Immigration of the Port of New York, recently made public. The increase is startling. Last year, of the 341,712 immigrants who passed through the portals of Ellis Island into this country, 79,088 over fourteen years of age, or 23.41 per cent., were unable to read or write their own language. This year, 107,323 of the 388,031 immigrants, or 27.66 per cent., were of this class. One of the causes given for this increase of more than 4 per cent. is the growing immigration from countries where the percentage of illiteracy is high. Nearly one-half of the steerage immigrants present an illiteracy of from 40 to 55 per cent. The nation sending the highest percentage was Russia. Among the 5,032 Ruthenians who came here from South Russia last year, 2,554, or 50.75 per cent., were illiterates. The nation which followed next, Italy, was close upon the heels of Russia. That country sent more immigrants than any other. Out of the 111,858 immigrants from Southern Italy, 56,104, or 50.46 per cent., had not the intellectual qualifications of an elector. North Italy sent 20,302 immigrants, of whom 12.45 per cent. were illiterates. The countries from which immigrants came in the order of their percentage of illiteracy are as follows: Scandinavia, Finland, Bohemia,

England, Scotland, and Wales, Ireland, France, and Germany, under 5 per cent.; Hungary and North Italy, under 15 per cent.; Hebrews, under 20 per cent., Spain and Greece, under 25 per cent.; Slovak, under 30 per cent; Croatia, Poland, and Dalmatia, under 35 per cent; Armenia and Syria, under 40 per cent; Lithuania and Portugal, under 50 per cent, and South Italy and Ruthenia, under 55 per cent.

Force and Frequency of the Respiratory Movements in High Altitudes.—Dr. William Bullock Workman and his wife have recently published a book, giving an account of their experiences of mountain climbing in the Himalayas. Their observations as regards respiration at high altitudes may be summarized as follows: "At about 15,000 feet an increase in the force and frequency of the respiratory movements is first noticed. The climber must now slacken his pace, and hold himself well in hand. At 17,000 feet to 18,000 feet, the change in the condition becomes decided, and from this altitude all movements must be made with deliberation. So long as the movements are slow and measured, no disagreeable symptoms should be felt, and Dr. Workman states that he has not noticed any marked increase in the severity of the quickened respiration between 17,000 feet and 21,000 feet. His pulse and respiration when resting at three different altitudes were as follows: 16,200 feet, pulse, 76; respiration, 17; 17,375 feet, pulse, 76; respiration, 18; 17,900 feet, pulse, 75, respiration, 18. From this it will be seen that an altitude of 17,000, together with the exertion necessary to attain such a height, had little or no effect on the pulse and respiration.

The Consumption of Sugar in the United States.—The total consumption of sugar in the United States last year was 2,219,847 tons, and based on the average increase of 6.34 per cent. during the past nineteen years, the consumption this year should be 2,360,585 tons. Of this quantity 1,000,000 tons in round figures will come from American sources, say Louisiana being able to produce 350,000 tons, United States beet factories 150,000, Hawaii 350,000, and Porto Rico 150,000, all being free of duty, leaving 1,360,585 tons to come from other sources, and on which duty is paid. The average duty assessed is $36 per ton, or a total of $48,981,060. The price of all the sugar consumed, however, being enhanced to the extent of the duty of $36 per ton, or a total of $84,981,060, it is evident that $36,000,000 additional is paid by the people in order to provide, the Government with $40,000,000 for revenue, of which the Government is not now in need. If the duty is taken off Cuba sugar, the benefit of $85,000,000 goes to the people. On October 8, the quotation for Cuba centrifugal sugar 96° test, free on board Cuba, was 1.96c. per lb., duty on same amounts to 1.685c.—equivalent to 86 per cent. ad valorem.

The Ameer of Afghanistan.—Much is being written in British journals and periodicals concerning the late despotic and fierce but able ruler of Afghanistan. The *Lancet*, October 12, has an article from the pen of Dr. Gray, who, in 1890, attended the deceased monarch. It appears that at the time the Afghan ruler was suffering from a particularly aggravated attack of gout, so serious did Dr. Gray consider his condition, that, although by the help of the English physician's treatment the disease was temporarily controlled, he estimated the duration of his patient's life at no longer than two years. Dr. Gray also relates some of the troubles which are almost sure to happen to the medical attendant upon an Eastern potentate. An Englishwoman, by name Hamilton, acted as chief medical adviser to the Ameer up to, and for several years before, his death. The lady is also said to have possessed a considerable amount of influence over the self-willed and bloodthirsty monarch.

Birds as Surgeons.—A well-known London lay weekly journal contains the following: "Certain birds are said to possess a wonderful knowledge of the principles of surgery. The woodcock, the partridge, and some others, we are told, are able to dress their wounds with marvellous skill. A French naturalist says that [illegible] sions he has killed woodcock that were [illegible] valescing from wounds previously received. In one instance he found the old injury neatly dressed down plucked from the stem of feathers and skilfully arranged over the wound, evidently by the long beak of the bird. In some cases a solid plaster was thus formed, and in others ligatures had been applied to wounded or broken limbs. If true, this is very interesting and would go far to prove Mr. Ernest Seton Thompson's contention that animals and birds are gifted with greater reasoning powers than the majority of persons imagine."

The Hæmaturia of Pregnancy.—Umberto Chiaromonte reports the case of a woman in good health, and with no family taint, or any lesion of importance, who suffered from hæmaturia which was probably of renal origin, which made its appearance about the middle of pregnancy and disappeared after labor. There was no discoverable lesion of bladder, ureters, or kidneys, no lithiasis, no hæmophilia, no parasites, no nephritic degeneration, and no retention. The case undoubtedly belongs to the rare type, only eight have been described in which pregnancy and pregnancy alone, is the etiological factor. It can therefore logically be called the "hæmaturia of pregnancy." As to the cause, it may be congestion, but only secondarily. It is more likely that the pathogenesis of this condition consists in a toxæmia from hepatorenal insufficiency.—*Annali di Ostet. Ginec. et Pat. infantile.*

A Malformation of the Female Genitalia.—S. Monsarrat describes a case remarkable not so much for the actual deformity, as for the [illegible] complications. The patient was a woman, twenty-three years old, who complained of dyspareunia, thus always being followed by hæmaturia. Examination showed a septum completely occluding the vagina, and perforated by a very small orifice which could be found only after considerable searching. The urethra was easily dilatable, and admitted the index finger, and it was through this that coitus regularly took place. But in spite of this relaxation, no incontinence of urine was present. On incising the occluding septum, which was one-fourth of an inch in thickness, the vagina was found very much constricted, admitting only a single finger.—*Centralblatt für Gynäkologie.*

Albuminuria for Sixteen Years, Without Perceptible Impairment of Health.—P. Maxwell Foshay reports the case of a perfectly healthy man in whom albuminuria has occurred at least intermittently for over fifteen years. The lesson to be drawn from the case is the necessity for extreme care in studying cases of albuminuria before coming to definite conclusions as to the permanence or evanescence of the condition. A three months' observation of such a case should determine its future course with fair accuracy. If the albumin is intermittent and of small proportion, if no casts, or only a few hyaline ones, occur at times, and if the vascular system at no time during the period exhibits any abnormality, a good prognosis may be given without hesitation.—*The Medical Examiner and Practitioner.*

The Absorbing Power of the Large Intestine.—Guido Barbiani concludes, from the results of his experimentation, that the large intestines have decided absorbing powers, less rapid, but quite as intense, as those of the stomach. These are greatest near the ileo-cæcal valve, less at the rectum, and least in the middle portion. The power of absorption can be increased by artificial means, either by the mechanical action of fluids projected by means of a syringe, or by chemical action of a liquid (sodium sulphate solution) which comes in contact with the mucosa. The intestines absorb medicinal substances much more readily than nutritive substances, even when the latter are predigested. Nutritive enemata are merely a temporary means of artificially prolonging life, but as such are useful.—*L. Policlinico.*

To Distinguish Between Smallpox and Chickenpox.—A writer in the *Lancet*, October 12, referring to the prevalence of smallpox in London and the difficulty sometimes in mild cases of differentiating between this disease and chickenpox, calls attention to a well-known method by which this object can be attained. The vesicles in chickenpox are unilocular, while in smallpox they are multilocular, the practical result of this pathological fact being that if a chickenpox vesicle be pricked with a needle, its contents can be completely evacuated, and the cell will collapse; whereas in smallpox, if you make twenty pricks with a needle, the vesicle will not collapse, because, being multilocular, it is impossible to empty it.

Hydrophobia and St. Hubert.—It is well known that St. Hubert (died A. D. 727) was reputed to cure hydrophobia by touch, as kings cured the "king's evil." The saint was a father before he was a saint, and left a son from whom descend a family—the Lavernots—still flourishing in Picardy. This family claims (and the claim is admitted throughout Picardy) to have inherited the magical powers of the saint, and exercises them regularly to this day. The neighbors still prefer their treatment to that of the Pasteur Institute.—*New York Sun.*

The Mother of Thirty-Seven.—The individual birth record, says *Tit-Bits*, must surely go to the wife of a farmer near Salzburg, in Austria. She has presented her loving, if perhaps astonished, husband with twins eight times in succession. As if this were not enough, she "went one better," and for three successive times brought forth triplets. Then there was a retrogression, the woman lapsing into twins for four times in succession, and afterward further injured her reputation by giving birth to singles on four occasions

Health Reports.—The following cases of smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, U. S. Marine Hospital Service, during the week ended November 2, 1901:

		CASES.	DEATHS.
SMALLPOX, UNITED STATES			
California, San Francisco	Oct. 13-20	2	
Indiana, Evansville	Oct. 19-26	7	
Kentucky, Lexington	Oct. 19-26	1	
Massachusetts, Cambridge	Oct. 19-26	1	
Minnesota, Minneapolis	Oct. 19-26	1	
New Jersey, Newark	Oct. 21-28	15	1
New York, New York	Oct. 19-20	8	3
North Dakota, Bottineau Co.	Sep. 15-Oct. 15	10	
Cass Co.	Sep. 15-Oct. 15	1	
Edmond Co.	Sep. 15-Oct. 15	0	
Mayville	Oct. 18-25	1	
Pennsylvania, Morristown	Oct. 19-26	5	
Rhode Island, Newport	Oct. 19-26	7	
Wisconsin, Green Bay	Oct. 19-27	4	
SMALLPOX, FOREIGN.			
Belgium, Antwerp	Sep. 28-Oct. 5	3	2
Ghent	Oct. 5-12		2
Brazil, Rio de Janeiro	Sep. 1-15		109
Canada, Halifax	Oct. 5-12	7	1
St. John	Oct. 19-26	6	
Colombia, Cartagena	Sep. 29-Oct. 6		2
Panama	Oct. 14-21	125	
France, Paris	Oct. 5-12		3

Samarang	Aug. 1-31	1,360	600

Therapeutic Hints.

Cod Liver Oil is invaluable in sciatica, lumbago, neuralgia, chronic rheumatism, advanced syphilis, as well as in tuberculous conditions.

Formaldehyde has been used with success in the treatment of ringworm.

Sulphuric acid, in minute doses, has long been regarded in Europe as a most efficient remedy for controlling persistent hiccough.

Nitroglycerin in 1-per-cent. solution (Spiritus glonoini) one drop t. i. d. increased to physiological effect is worth trying in sciatica.—*Pennsylvania Medical Journal*, August, 1901.

Prevention of Abortion.—Peter Horrocks (*Medical Press*, August 21, 1901) advises:

Avoid overstrain, shock, and fright. Operations not to be performed unless needful, especially extraction of teeth.

Avoid using instruments about uterus and cervix, and also avoid syringing. Pessaries should not be worn after the fourth month.

Purging should be avoided, and enemata, specially with turpentine or glycerin. Constipation should be avoided. Pelvic tumors may be pushed up into the abdomen or even removed. Endometritis must be cured. Cessation from coitus often permits of gestation progressing to term. Uterine displacements must be remedied. Avoid tight lacing.

Certain ecbolic drugs must not be given, such as ergot, savin, digitalis and quinine, lead.

Syphilis should be treated in both father and mother, and very often it is useful to give small quantities of mercury throughout pregnancy. General diseases must be treated with the appropriate remedies. Over-suckling should be avoided

Trachelorrhaphy sometimes enables the ovum to remain in the uterus.

Alcohol should not be taken to excess, and in most cases should be avoided altogether.

High pyrexia from any cause should be brought down by cold baths, etc.

Hints to Dyspeptics.—Eat slowly, masticating the food very thoroughly, even more so if possible than is required in health. The more time the food spends in the mouth, the less it will spend in the stomach. Avoid drinking at meals; at most take a few sips of warm drink at the close of the meal, if the food is very dry in character. In general, dyspeptic stomachs manage dry food better than that containing much fluid. Eat neither very hot nor cold food. The best temperature is about that of the body. Avoid exposure to cold after eating. Be careful to avoid excess in eating. Eat no more than the wants of the system require. Sometimes less than is really needed must be taken when digestion is very weak. Strength depends not on what is eaten, but on what is digested. Never take violent exercise of any sort, either mental or physical, either just before or just after a meal. It is not good to sleep immediately after eating, nor within four hours of a meal. Never eat more than three times a day, and make the last meal very light. For many dyspeptics, two meals are better than more. Never eat a morsel of any sort between meals. Never eat when very tired, whether exhausted from mental or physical labor. Never eat when the mind is worried or the temper ruffled, if possible to avoid doing so. Eat only food that is easy of digestion, avoiding complicated and indigestible dishes, and taking but one to three kinds at a meal. Most persons will be benefited by the use of oatmeal, wheat meal, cracked wheat, and other whole-grain preparations, though many will find it necessary to avoid vegetables, especially when fruits are taken.—*Public Health Journal.*

PATHOLOGY AND TREATMENT OF MIGRAINE.*

BY WILLIAM H. THOMSON, M.D., LL.D.
NEW YORK CITY.

IT is particularly in functional nervous diseases that the subject of etiology is of such practical importance. In the case of migraine it is not too much to say that the line of treatment will be determined mainly by the answer given to the question, whether the affection be due to a nervous disease or to a toxæmia. We will, therefore, discuss this question first, for there is little need to refer to its symptoms or accompaniments when these have been better detailed than might be expected for any other malady, owing to the fact that so many eminent medical men have had full occasion to observe them in their own persons, and have described them accordingly.

In favor of migraine being due to a specific derangement of some part of the nervous system, the predominance of purely nervous symptoms is cited. The severity of the pain; the peculiar derangements of vision; the common limitation of the headache to one side, as if its chief seat were in one cerebral hemisphere; the mental sluggishness which accompanies it; and the frequent radiation from the head to the extremities of various sensory disorders, analogous to like symptoms in affections of the central nervous system, have led many authors to regard it as the manifestation of a faulty nervous organization. The undoubted fact that migraine is more distinctly hereditary than any other nervous disease, or, in fact, than almost any disease, is held to be strongly corroborative of the supposition that it is caused by an original constitutional defect in nerve nutrition. The primary seat of this defect is variously surmised, though, owing to the numerous signs of vasomotor derangements during the attack, many writers hold that it is the sympathetic nervous system which is chiefly involved.

The treatment for migraine, which such theories of its nature and pathology suggest, is sufficiently illustrated in the following recommendations to be found in one of the latest publications on the subject.[1]

"It is difficult for most sedentary persons to accumulate that measure of bodily vigor which is necessary to combat the returning attacks of migraine. In the next place, dietetic and medicinal rules should be adopted which may favor the development of more robust health. Careful regulation of the diet, so as to avoid the errors of feeding which are so common among the classes above specified, and the adoption of a dietary containing nutritious and easily assimilated food will do much to lessen the frequency of the attacks. Medicines, such as quinine, iron, nux vomica, nitrate of silver, will be found beneficial mainly for their tonic properties. Any tendency to constipation should be corrected. For those patients in whom the attacks recur with great frequency, and for those in whom the 'status hemicranialis' is established, it is often necessary to employ remedies to give the patient some immediate relief. For this purpose, nerve sedatives, judiciously administered, are beneficial, and of these I have found the bromides, particularly the bromide of ammonia, most beneficial. In extreme cases, the drug should be pushed until slight persistent drowsiness is produced. The patient not only sleeps better, but the attacks often disappear under its use. Then, after a week or two, the employment of tonic medicines and hygienic regulations lead usually to satisfactory results. When the more severe attacks are impending, no remedies appear to be of any avail, whether in stopping the attack or lessening its severity. Frequently, however, the milder attacks may be cut short by this remedy or that, and the most efficacious of these is found in the class of drugs represented by phenacetin and antipyrin. Among other remedies which have also been found beneficial in modifying an attack of migraine are caffein, guarana, cannabis indica, and salicylate of sodium. When the pain is so severe as to be almost unbearable, relief can only be obtained by the judicious use of such exceptional and occasional means as inhalation of chloroform vapor or the subcutaneous administration of morphine."

What such a scheme of treatment amounts to, is some good advice that the patient should observe the laws of health, take "tonics," if needed, and, when he has sick headache, try an empirical list of sedatives. It shows no guiding principle based upon the cause and nature of the malady, and it would prove totally inadequate for really severe cases; yet, it is only severe cases which should be chosen to furnish the test of the efficacy of any form of treatment, for the great majority of the sufferers from migraine have their attacks but now and then, and but for one day. The recovery is complete and apparently spontaneous, and but for these occasional relapses they, as a class, lead active and enjoyable lives.

Very different is the experience of others whose lives become burdensome with repeated recurrences of the worst kinds of suffering, accompanied with a variety of distressing symptoms and with deathly prostration, from which they scarcely recover and begin to resume their daily occupations before the dread visitation is on them again. Not infrequently the general health becomes deteriorated, and they become both emaciated and anæmic. Such patients are the despair of their medical advisers, for all varieties of drugs and of prescriptions are tried and abandoned in turn, just so long as the conception of the disease being a neurosis continues to be held by the physician.

We would, therefore, approach the subject of the

*Paper read before the New York State Medical Society, October 16, 1901.

[1]Article on Migraine in "Allbutt's System of Medicine," by Dr. James McKenzie.

pathology of migraine from quite a different standpoint.

In the first place, it cannot be ranked among the class of nervous diseases to which the term degenerative can be applied, like a trigeminal neuralgia which comes on late in life; for migraine is not only a disease of youth and of the prime of life, but it actually declines and generally ceases after fifty. Nor can its victims be called degenerates compared with their fellows. Gowers enumerates among its sufferers, and who made it a study, the celebrated Dr. Fothergill, Marmontel, Haller, Wollaston, Du Bois Raymond, Wheatstone, Sir John Herschell, Sir George Airy and his son, Sir Hubert Airy, who gave a very interesting account of his ocular symptoms in the "Transactions of the Royal Society."

On the other hand, there are whole classes of people who never have migraine. They may furnish their proportionate quota to other nervous derangements, but not to migraine. Why not, is a question which must be studied, because migraine itself is a class disease; that is, just as one class of persons do not have migraine, so we find that others suffer from migraine in a common proportion. They may differ in everything else, but in liability to migraine they are all alike. There must be some explanation for this contrast, and that explanation we shall find to come very close to the root of the matter.

Those who do not have migraine are sailors, agriculturists, miners, truckmen, carpenters, and all outdoor laborers without exception. Those who do have migraine are clergymen, students, professional men, brain and not muscle workers, housewives, shop girls, needlewomen, and indoor people generally, and, therefore, more commonly women.

There is certainly no accounting for two such opposing lists by class differences in cerebral organization or in their sympathetic ganglia. But there is a great class difference which is as unmistakable as it is significant, viz., in the physical habits of life; or, to be more precise, in those physical habits which most affect the portal circulation.

This portal circulation is necessarily the weakest in its share of the propulsive power of the heart of any department of circulation of the body, and the most dependent, therefore, on adjuvants external to itself. It constitutes a current great in volume, at all times equal to about one-fourth of the mass of the blood, but intercalated, not upon the direct arterial, but upon the returning venous current, and delayed further by having to course through a second capillary system in the virtually non-contractile tissue of the liver. Moreover, its vessels, including its accompanying lymphatics, are the most tortuous in the body. By far its most important adjuvant is the powerful mechanism of the muscles of respiration, especially the diaphragm and the abdominal muscles. No better illustration of this fact is found than in the secretion of bile, a fluid of markedly low specific gravity, about equal in its daily amount to that of the urine, but secreted at so low a pressure that it might almost be compared to a simple leakage, as we find that the most moderate obstruction in its channels, such as catarrhal swelling of the mucous membrane of the bile ducts, suffices to cause jaundice.

Now, it has been experimentally demonstrated that the active movements of the over-arching diaphragm alternating with the active contraction of the abdominal walls, especially in deep breathing greatly increase the flow of the biliary secretion—a fact also illustrated by the serious results of phrenic paralysis in disease on the whole abdominal circulation. Now, add to this that both the pulse force and the frequency of the general circulation fall at once in a sedentary compared with a standing posture, let alone the greater change still from general exercise, and there cannot but be the most material difference between the portal circulation of the farm laborer, strongly compressing and relaxing all his abdominal muscles in deep breathing while at work, and the relative total inaction of the same muscular apparatus in the brain worker at his desk, or the needlewoman at her sewing. Biliary stasis accounts for the statistics of our post-mortem tables, that after fifty one woman out of every four has gallstones. But stasis in the liver involves stasis also in the entire gastro-intestinal tract, and that, in turn, implies both imperfect digestion and chronic constipation.

If, however, imperfect digestion were all that chronic portal stasis implies, it would have but little bearing upon our present subject. Rather, we may say that modern research is increasingly demonstrating the poisonous properties of the products of imperfect digestion, and, what is more, has experimentally proven that some of these products are exclusively nerve poisons. There are many observations which also go to show that one of the great functions of the liver itself is to neutralize gastro-intestinal nerve poisons, so that, when its functions are experimentally interfered with, prompt poisoning with distinctively nervous symptoms follows. In short, there is not a headache, nor a neuralgia, nor a vasomotor derangement, familiar to us, among the symptoms of migraine which cannot be produced by poisons manufactured in our laboratories out of the elements of our daily food by subjecting those foods to conditions similar to those present in abnormal digestion in the alimentary canal.

What the actual poison is which may be the agent that produces migraine, we are not yet able to demonstrate. Analogy with the facts of drug poisoning indicates that it may be but minute in amount. I have seen in susceptible persons, especially in women subject to migraine, a small dose of morphine produce intense headache, total suspension of digestion, nausea, vomiting, and extreme prostration, besides marked vasomotor disturbances. Hence the whole contention, that the varied nervous symptoms of migraine point to it as being a nervous malady, falls to the ground when confronted with the familiar facts of toxæmia induced by our long-known nerve poisons. There is also no one fact better established about ordinary drug poisons than their peculiarly selective action. Not one of them acts on all nervous functions, but rather picks out one or more of them so definitely that we recognize their presence in the blood by the special symptoms which they cause. In other words, each of them, while acting, produces a special nervous malady, with its own characteristic sequence of disturbance of nerve functions, precisely as we note a characteristic sequence and grouping of symptoms in migraine itself.

The fact that migraine is notably a hereditary, or, in other words, a family, complaint is accounted for easily on the toxæmia hypothesis by the parallel fact that there is nothing so hereditary as peculiarities of digestion and of indigestion. Even some acquired derangements of metabolism, such as gout, which practically is a disease prevailing only where fermented liquors, in distinction from spirits, are used, become in time as hereditary as migraine.

On the other hand, it is in the case of blood poisons alone that we have any analogy to the

striking intermittency of migraine. A true nervous disease may remit, but it never intermits. Its presence can always be detected if carefully looked for. But the most experienced neurologist would be unable to foretell that the vivacious guest next him at dinner will in two days be utterly prostrated with a return of an old migraine. And in the case of more than one well-known blood poison much the same thing happens. The poison of gout may be circulating in the veins for days, and yet not until some midnight hour explode in an attack of gouty asthma. A sudden attack of uræmic convulsions always implies a uræmia long antecedent to that unexpected nervous derangement, and a like explanation of the cumulative process of a blood poison in migraine is far more probable than Liveing's fanciful theory of a nerve storm.

Views of pathology, however, are only of academic interest so long as they do not supply data for practical applications. I hold that therapeutics is a test of pathology. If a theory does not bear fruit in suggesting lines of successful treatment, by so much is it discredited. It is because I feel that I have been justified by results in the management of severe, and not of ordinary, cases that I would close with a brief outline of what I may term the antitoxic treatment of migraine.

In the first place, all disorders that are due to contravention of physiological laws must be treated by a return to obedience to those laws. Migraine is one of the penalties exacted for neglect of the means provided by nature to assist the portal circulation, and to keep it free and active. If the persons so affected will continue to lead such sedentary lives that practically half of nature's apparatus for that end is left unused, they must pay the penalty in feeble and imperfect digestion with consequent clouding and suffering of the nervous system from chronic poisoning. But how to meet this indication for securing habitual activity of the portal system is often practically one of the most difficult undertakings for many patients under the conditions of modern civilization; and it must be left to each physician to devise his measures for each individual case.

We are, therefore, most commonly obliged to have resort to medicinal means and regimen for prevention of the attacks in the first instance, and then for the alleviation of them when they do occur.

First, therefore, as to prophylaxis. All severe cases, without exception, are chronic dyspeptics, and of this one of the commonest symptoms is chronic constipation. A mercurial laxative, such as a five-grain blue pill at night, with a saline in the morning to secure its action, is a weekly prescription of mine which I strongly insist upon in every case, to be kept up for months together. I am sure that we do not possess a more certain intestinal antiseptic than a mercurial cathartic, and I never feel satisfied when a patient for any reason declines to persevere in its employment. As a further systematic measure for this purpose I prescribe from one to two drachms of the sulphate of soda, with ten grains of sodium salicylate in a tumbler of *hot* water, to be sipped down every morning on rising. With some, however, the sodium phosphate is preferred, though I do not think it is as effective as the sulphate. Then, half an hour before each meal, a pill is prescribed of one-twentieth of a grain of bichromate of potash, with three grains of bismuth subcarbonate. Half an hour after meals and at night full doses of intestinal antiseptics in the form of ten grains of phenol bismuth or naphthol bismuth, with ten grains of ammonium benzoate or sodium benzoate, are given in two capsules.

While the benzoates are among our best intestinal antiseptics, yet our prescriptions of that nature ought to vary in different cases or at different times in the same case.

Thus, not uncommonly, the signs of intestinal derangement include diarrhœa instead of constipation, and a brief recital from a case in my notes illustrates both how our prescriptions may be varied, and how extensively distributed may be the toxic nervous symptoms of a bad case of migraine.

Mrs. C., aged thirty-five years, came in June, 1899, for early morning diarrhœa of four years' standing. She was frail looking, anæmic, and emaciated. Has a great deal of nausea and fears going about alone on account of "spells," when her jaw drops and she becomes unconscious, often for twenty minutes or half an hour, without any twitching; and when she recovers consciousness she feels as if her whole body had lost sensation, except the joints, which all seem to ache together. At other times, she has strange feelings come on, with a tight sensation in the jaw which drops, and she has then to sit down at once. She has cramps in the left muscles of the neck, in the right arm and the left leg, with much nocturnal aching in all the extremities. With every one of these attacks she has flashes of rainbow colors till she becomes quite blind; at other times she has for hours a scotoma before the right eye and a distressing dizziness. Her attacks of unconsciousness come on about every three weeks, but the nausea and headaches occur between times so often that she rarely passes a well day. She was ordered to abstain altogether from red meats, to take a blue pill twice a week, a pill of one-twentieth grain kal. bichromat. with bismuth before meals, with two drachms of sodium phosphate and ten grains sodium salicylate in hot water on rising, and an hour after meals ten grains each of phenol bismuth and sodium benzoate. In a few weeks she wrote that the last-named capsules made her nauseated. A prescription of

℞ Salol ... .. ʒij.
Bismuth subgallate ʒj
In 24 powders.

one-half hour before meals and at night, was substituted, with a dessert spoon of pancreatic emulsion half an hour after meals for her diarrhœa.

The note on August 23 was that she was improved in all respects, with subsidence of all her nervous symptoms. Had only one attack of feeling nervous since last report, and has gained in weight and in color. The last note is February 27, 1900. Looks very well, has no headaches nor any of her old symptoms, but finds that she cannot long omit the blue pill, and she likes to resort frequently to a prescription of October 15, which was

℞ Salicine ... ʒij
Ac. benzoini ... .. ʒss
Bismuth. subcarb ... ʒvss.
In forty-eight capsules. Two [illegible] d

Now, this case might easily have been mistaken for epilepsy, but the accompanying symptoms were those of a migrainous toxæmia, and she recovered without taking any bromide. The blue pill, instead of increasing her diarrhœa, seemed to check it, and she always felt better in her general state after it.

One aggravated patient referred to me from an inland city found, during last summer, her attacks much diminished both in frequency and severity (they usually prostrated her for three days), and she gained fifteen pounds in weight; but this September she had two sharp attacks. I changed

from the phenol bismuth and benzoate to Dr. M. Allen Starr's prescription of

℞ Sodium sulphocarbol . . . . . gr. v.
Kal. permangan. . . . . gr. j.
Betanaphthol . . . . . gr. j.

One after meals and at night,

the capsules being shellac-covered to prevent their solution in the stomach. As she suffers from chronic constipation, she took

℞ Sodium sulphate . . . . . ʒj,
Sodium phosphate . . . . ʒiij,
Sodium salicyl. . . . . ʒij.

Divided into twelve powders,

one taken in a full tumbler of water as hot as she could sip it on rising. She took, besides, fifteen grains of the glycerophosphate of soda after meals. I have just received word from her that she feels much improved, and she still particularly praises the effect of the blue pill.

Prophylaxis is the main indication in the treatment of this complaint; but for the attacks themselves, when severe, the fluid extract of ergot given in drachm doses with a drachm of elix. cinchona in water, by stomach or by rectum, is the most certain agent in my experience to cut the attack short. The patient should lie perfectly still after taking it till all pain passes off, and in some cases the dose may be repeated after two or three hours.

In those who cannot take the ergot without vomiting, I rely on ten grains of lactophenin with two grains of caffeine citrate, repeated every two hours until relief occurs; or fifteen grains of antipyrin, always taken with a teaspoon of aromatic spirits of ammonia.

Diet is a matter of great importance, because I believe that in every severe case the red meats should be abstained from altogether, or, at least, never taken at night. In other respects the digestive abilities and inabilities of each patient must be individually studied, as all experienced practitioners well know. Whatever is indigestible for any person is by that person to be avoided, but I find no general rule for this purpose except one, and that is that if any article either of food or of drink is tasted again in an eructation from the stomach, it is a notice from the stomach that it does not want any more of that stuff, and that as a finality.

All nervous functional diseases have their exciting causes as well as their permanent causes. The exciting causes should never be confounded with the permanent causes, as they often are, as if all that we have to do is to prevent them, and then the disease will cease. Now, the commonest exciting cause of migraine is overtaxation of the nervous system, whether by thinking or by feeling, and likewise by undue exertion of the voluntary muscles. On this account, migraine belongs to the worrying and restless periods of life, and then declines with the greater repose of old age. I have been struck in cases of persistence of migraine in elderly persons that it seems always connected with continuance of causes of mental anxiety and depression. It is in them that we have to fear the development of melancholia, and against that dread malady in turn I know of no better prophylactic than the measures for intestinal antisepsis which have been outlined for the treatment of migraine.

25 East Forty-seventh Street.

Medical Mortality in South Africa.—Six medical officers have been killed, nine have died of disease, twelve have been wounded, three civil surgeons have been killed, eleven have died of disease, and five have been wounded. Of all branches, including orderlies and nurses, nearly four hundred medical helpers have fallen victims to their labors.

THE PRESENT POSITION OF OPHTHALMIC SCIENCE AND ART.*

By D. B. St. John Roosa, M.D.,
New York

Ophthalmology is one of the oldest of the specialties of our science and art. That it is properly so, has been almost unanimously acknowledged by the profession from the beginning of the time when surgeon oculists began to exist, which may be said to be, in round numbers, perhaps one hundred years ago. Since then, and especially in the last fifty years, ophthalmology has grown so luxuriantly in its various fields, that it has become subdivided, in some few instances, as a specialty. Here and there, members of the profession have devoted themselves almost exclusively to the correction of defective vision by the adjustment of glasses, while inflammatory conditions, or infections, and those requiring operation, have been passed on to others, who, in their turn, paid relatively little attention to optical defects. An attempt has also been made by some manufacturing opticians in various parts of the world, without an education in general medicine, to assume the care of all the conditions of the eye requiring glasses. In this State they have sought legislation to constitute a separate professional class, and yet this class of opticians has never contributed anything at all essential to our knowledge of the conditions of the eye requiring glasses, or to that pertaining to the character of lenses to be used. Such a subdivision, either in the profession or out of it, if generally made, would be detrimental to the interests of the public, and, on this ground, should never become a system of practice. The specialties in medicine have reached, perhaps, their utmost limit. There will be always a large rank and file of all-round men of the first order, and those who are at work in special departments should be able, when necessity occur, to become fair general practitioners. Our ideal practitioner is not one who knows a great deal of one thing and nothing at all of others; but, rather, one who knows a great deal of many things, and who must devote himself to some special investigations for the greatest good of the greatest number.

But I may not dwell on this interesting inquiry of how far "specialism" is beneficial to the human race, and what limits should be put to it. I pass on to the subject of the hour, and I propose to inquire with you, How stands now ophthalmic science and art, since its great masters—those who placed it in the van of the progress of medicine—are gone? Mackenzie, Sichel, Donders, Graefe, Arlt, Jaeger, Horner, Desmarres, Bowman, Critchett, Wilde; in our own country, the two Williamses, Agnew, Loring, Noyes, and many others, an enumeration of whose names is a recognition of their great service to the race. How have they left the field, has all the needful work been done by them, and have we reached a point where we simply cultivate plants, already well grounded in a soil well prepared by our predecessors? Our answer to all this must be qualified. There are certain departments of ophthalmology in which no essential advance or discovery has been made in the last twenty-five years. After Helmholtz gave us the ophthalmoscope, if we had stopped with his plane mirror, difficult to manage, and not to compare with the simple instrument of Liebrech and his contemporaries, we should have been handicapped with an imperfect method of examination. All that Helmholtz did—but what a mighty *all*—was to provide us a means—imperfect it is true, but a means—for doing that which was hitherto impossible—of examining

*Read before the Medical Society of the State of New York, October 16, 1901.

with tolerable but not complete ease the retina, the choroid, the vitreous, the lens, and the optic papilla.

Until this time, while here and there were even exhibitions of luminous eyes, no one found out the means of making them so, and the principle of optics upon which this illumination depended. One of our own number, Edward G. Loring, gave us the final contribution to ophthalmoscopy—an instrument by which we could thoroughly and easily determine the refraction of the eye. The tilting mirror, suggested by Wadsworth of Boston, made a perfect instrument, as it remains to this day. If no modifications had ever been made since these two men gave us the perfected instrument, ophthalmology would have lost nothing of importance which may be revealed by an ophthalmic mirror. Yet, no sooner was Loring's ophthalmoscope announced and described, than modifications and alterations, chiefly of a trivial character, began, and none but the tilting mirror was important.

Helmholtz also invented the instrument for measuring the radius of the cornea—the ophthalmometer. Helmholtz first did the thing, and gave us the instrument by which an expert in a laboratory, with plenty of time at his disposal, could make a corneal measurement. Valuable results came from the use of this ophthalmometer, or keratometer, as perhaps it should be called. One of our own members, Knapp, with Donders, was the first to avail himself of the instrument as then presented, as well as Dyer, in this country.

But these arduous labors were scarcely ever repeated, and the ophthalmometer of Helmholtz passed into the limbo of unused inventions until, after many years of research and trial, Javal, a French Alsatian, and Schiotz, his Norwegian assistant, at the Sorbonne in 1881, gave us an instrument by which an ordinary practitioner, after a few hours of experience, under a teacher, may, in two or three minutes, accurately determine the vertical, horizontal, or oblique radius of curvature of the human cornea. Here, also, the work of modification immediately began. But, as after Loring the ophthalmoscope was invented, so the ophthalmometer, as left by Javal, remains entirely satisfactory for its important purposes. The general use of the ophthalmometer is rapidly simplifying our methods of determining the proper glasses to be worn by those who have marked optical defects. I say "marked" advisedly, because we have learned that many departures from a so-called normal condition may exist, without any necessity for the wearing of glasses. The ophthalmometer does its great work because, on the very threshold of our investigations of the refraction of the eye, it quickly determines that which was formerly difficult but always important to learn—the presence or absence of corneal astigmatism of any degree, high or low.

If we consider the present condition of inflammatory affections of the conjunctiva and cornea, while it is not at all certain that a greater number of cases are cured than under the old methods, which still retain their usefulness, certainly our knowledge has become much more exact since the discoveries of Lister and Koch and Weeks, and we have learned of aseptics and antiseptics and bacilli, and we know why we use silver nitrate and copper sulphate, and so on. We had been using antiseptic remedies without knowing exactly in what specific way they acted, if, indeed, we are now sure. As has been intimated, nitrate of silver, sulphate of copper, alum for the conjunctiva, and carbolic acid for the cornea were used long before the present supposed principle of their action was known probably with as great success. The ophthalmia of the new-born, however, now receives immediate and rational treatment, and the frequency of the continuation of the infection has been very much diminished by Credé's investigations.

In trachoma, the mechanical treatment has made a great advance in our means of relief. We have also learned the contagiousness of all conjunctival affections, as we did not know it before. A United States examining surgeon will now send back a European immigrant affected with trachoma, realizing, as he does, the importance of not spreading this condition, so likely to be destructive to sight. The writer of this discourse actually encountered, on a vessel going to Liverpool, through the courtesy of the ship's doctor, two Finns, who had been wisely rejected by our authorities as not being proper immigrants to enter this country, because they were affected with trachoma, which, to the credit of the American examining officer be it said, could not be detected except by a thorough turning over of the upper lid by a little manipulation not always easily accomplished, except by an expert.

A great advance has been made in the treatment of myopia of a high degree by the invention of the method of lessening the refraction of the eye by removal of the lens. Very high degrees of myopia, as is well known, are so disabling as to be worthy of relief in this manner. From my own observation, in Swiss and German hospitals, I judge there are more cases in those countries of such degrees of myopia than in France, England, or our own country.

In the matter of strabismus, advance has been slow, and not widely spread. We are not yet fully in the open. This, I am inclined to think, is due, in some part, to the excessive zeal and enthusiasm exercised by those, especially in our own country, who were led astray by the astonishing revelations of the value of glasses in hypermetropia and astigmatism. A large class of people, up to the time of Donders, were, except in isolated cases, left without aid to their vision, although the means of relief were actually at their side, though unseen. These enthusiasts, going very far beyond the masters, beside the cure of headaches and defective eyesight, found in errors of refraction the source of epilepsy, idiocy, chorea, and a great number of diseases of the nervous system. They claimed that "difficulties attending the functions of accommodation and adjusting the eyes in the acts of vision, or irritations arising from the nerves involved in the process, are among the most prolific sources of nervous disturbances." Driven from their untenable position by the exact observations of those who followed them, they took refuge in a position in which they are still in some force. Again, I say, *especially* in this country. The claim now made in certain quarters is that in the want of exact equilibrium of the eyes, very often latent and only to be determined by a measurement of the power of given muscles, at certain times, is to be found the source of a large class of diseases, whose origin has been hitherto unsuspected. This later theory of the great importance of a latent defect has been much disturbed by measurements of people in good health, without asthenopia, who were found to have exactly the same conditions that were supposed to do so much harm. But the results of the practice of division and partial division of the ocular muscles for the relief of these conditions, which were often unsuspected by the patient, and only with difficulty to be determined by the observer, soon excited grave doubts as to whether, after all, the whole human economy depends on the question of the action of the muscles of the eyeball. And all this, as I have intimated, led to a neglect of the study of a positive condition, strabismus, a deformity which

leads not only to blunting of the vision of one of the eyes, as now may, I think, be safely said, but also produces a marked deformity, which gives rise to great mental trouble to many of those affected with it, and gives them a distressing appearance to the observer. But in our time this is being studied, and we are moving toward positive rules of action, although much diversity of sentiment exists as to the proper methods of operating.

Javal and Panas in Paris, and their followers in this country, have done very much to rescue this subject from the field of mistaken conclusions in which it was left by Graefe, and which were increased a thousand-fold by mistaken zealots in this country. The study of so-called "latent squint," and of concealed irregularities and deficiencies in the action of the ocular muscles, has delayed very much what is, I hope, before us for its relief, in Javal's methods of obviating the necessity for operations in many cases, and Panas's rational operations when necessary. We are now much more sure of what we can do, and that is to restore the normal position of the eyes, and, in rare cases, to secure binocular single vision.

The mistaken conclusions of Dieffenbach, who first proposed operative means for the relief of strabismus about fifty-five years ago, led to sanguine hopes which could not be realized, for the deformity was supposed to depend upon something morbid in the muscle. This, at the most, we now know to be a spastic condition, while the origin of strabismus, as Donders endeavored to show, is found in fixed conditions of the eyeball.

In senile cataract, we have made most satisfactory advance. Formerly operators, as distinguished and skilful as Graefe, Arlt, Desmarres, Agnew, and Williams, might perform ideal removals of the lens, in the best technique of the time, and yet suppuration and destruction of the eye result. After the general introduction of Graefe's narrow knife, instead of the old broad instrument, the percentage of losses was sensibly diminished. But, until aseptic treatment was fully understood and practised, and a local anæsthetic, cocaine, provided by Koller, the most bitter disappointment often befell the most skilful operators. Now, that the instruments can be so cleansed that they are incapable of carrying infectious disease, and the dressings made absolutely aseptic, and the eye made perfectly insensible to the pain of the operation, the cases of suppuration have diminished to such an extent that a patient in fair health, with cataract, has better chances of a good result, with an operator of average skill, who is exact in his aseptic technique, than he formerly had in the hands of the most renowned operators of the world, when the causes of failure to heal the wound by "first intention" were utterly unknown, and when the patient might ruin his eye by his own movement during the operation, or in the vomiting from the effects of the ether.

In the matter of after-treatment of the capsule, and of iridectomy coincidental with the corneal sections, much of interest remains to be said to specialists. Here the most diverse opinions are still held. No common ground has been reached, and much remains to be done before we are agreed on all these points. But this we may say, that the chances of good vision in our time have been raised from, say, 60 per cent. to 90 per cent., by cocaine, the narrow knife, and aseptic treatment of the dressings, the instruments, and the eye.

We are also in an advanced position in the matter of operative procedures for the removal of iron and steel foreign bodies. The use of the magnet, first, the smaller ones, and, finally, the great one, invented by Haab of Zurich, have greatly facilitated these removals. In what proportion of cases, after the thorough removal of the septic body, it may still destroy the eye, remains to be shown. For the entrance of a foreign body into the eyeball, through the ciliary region, in spite of its thorough removal, will generally involve the loss of the eye as complete as that of a plate of glass when broken by a stone. But the removal of the foreign body, without great damage to the tissues in the process, gives us hope that we may lessen the cases of complete loss, and, better still, perhaps, of sympathetic iridochoroiditis.

The questions of the complete or partial enucleation of the eye for cosmetic purposes, or the prevention of sympathetic inflammation, the use of glass balls, and the like, as a substitute for the vitreous humor, are still widely discussed; but there exists no doubt in any mind that the eyeball must be, as to its principal part, promptly removed, should it be in danger of exciting sympathetic inflammation. The discovery, by Bonnet, of the method of enucleation of one eye for the relief of the other, however it may be done, still has the complete sanction of the profession. This, of itself, has been a tremendous advance.

In acute glaucoma, the same triumphs are achieved to-day as when Graefe first operated on the Berlin shoemaker. But when we come to speak of chronic glaucoma, we have a disease which may be mitigated, and whose advance may be delayed, but whose cure, as yet, remains usually impossible. While thousands of patients have testified by their rescue from blindness to the value of iridectomy in the acute form, yet it is only a few years since a New York surgical teacher considered the removal of a piece of iris, for glaucoma, as senseless an operation as would be the removal of a part of the peritoneum for peritonitis. It is only with a patient with an insidious narrowing field of vision, intermittent attacks of increased tension without pain, that we are tossed on a sea of doubt, in spite of the value of iridectomy in acute disease. It is possible that much remains to be done in the classification of what may be called "non-inflammatory glaucoma," and the new operation of removing the cervical ganglion of the sympathetic nerve is worthy of a fair trial.

Thanks to the thousands of investigators, and the excellent drawings of many of them, our knowledge of interior ocular accidents and infections—retinitis hæmorrhagica, retinitis syphilitica, optic neuritis, choroiditis, atrophy of the optic nerves—becomes more and more exact. But this knowledge does not, in every case, lead to hopes of cure. Detachment of the retina, probably always, except in traumatic cases, preceded by diseases of the choroid and vitreous, remains disastrous and incurable. Advance here must be looked for in prevention of the condition which makes detachment possible.

It is useless to hope that all disease is to be cured, or, as I should rather say, prevented in our time, whatever future ages may have in store for the human race. But we all admit that an exact and thorough diagnosis mitigates much of even incurable disease, and ultimately leads to better results. Certain it is, that in no department of our science and art are there more brilliant results of cure and relief by mechanical and operative interference than in what is known as ophthalmology.

With advantages much less than those to be obtained on the Continent of Europe, we, in this country, have made a good showing in the progress of the last fifty years. Could there be secured to us in the large cities better facilities for more exact and thorough observations, without regard to the pressing claims of private practice, much more would be achieved in American laboratories, hospitals, and infirmaries.

THE OFFICIAL RELATION OF THE MEDICAL PROFESSION TO PRIVATE CHARITABLE INSTITUTIONS.*

By ENOCH V STODDARD M D
ROCHESTER, N Y

It is not generally or fully appreciated that the relation of the medical profession to the systems of public aid and private charitable effort of this commonwealth is a very direct one, differing in some essential particulars from any other. This is due to the fact that a large proportion of such effort is of an eleemosynary character, involving a fixed establishment or so-called "institution." It is to this special field that the considerations of this article are directed.

The term "public charity" is a misnomer, and, being frequently employed, in reference to public aid, not only proves misleading, but tends, at times, to throw discredit upon true charitable effort. Charity is a matter of sentiment largely, and belongs to the individual. The aid given by society to its indigent or defective members is a matter of business policy almost entirely, the small degree of sentiment connected therewith being merely humanitarian.

The body social has learned that the indigent become discontented and dissatisfied, and that it is but a short step from a discontented condition to one of more or less violent demonstration against established regulations regarding property or individual rights.

The relation, therefore, of the medical profession to systems of public aid is different from its relation to private charitable institutions—the former presenting a business aspect, while the latter are, or should be, almost exclusively altruistic or eleemosynary in character.

It is not the purpose of this article to discuss the relation of the profession to State or municipal establishments for aid, since this is reasonably well defined from the fact that professional services rendered in this connection involve a pecuniary consideration. But to private charitable efforts the relation of the profession is very different, from the fact that the initiatory movement is from sentiment, and the element of compensation rarely enters into it.

The eleemosynary feature of medical service is a prominent one and may be traced in all epochs of man's progress in civilization. Probably in no period of history has altruistic effort been so universal in society, among the most advanced nations, as at the present time. It is a question of importance, therefore, to consider whether the elements concerned in such effort, and which render it effective, are rightly directed and are proceeding along proper lines.

Another somewhat misleading term in this connection is what is denominated "medical charity," it being applied to that class of institutions, or of organized effort, which is based upon aid extended to the indigent or unfortunate, who may stand in need of medical or surgical services, either to relieve temporary disability which prevents self-maintenance, or that of the family, or may be required by those who are in a chronic condition of disability and dependence.

In the first class would be included hospitals for acute diseases and surgical cases, and "out-patient departments," or dispensaries.

The second class would embrace the large number of institutions for the protracted care of the so-called incurable or chronic cases, the permanent homes for the aged and the enfeebled, for children and adolescents; the latter class including, also, correctional institutions.

The relation of the medical profession to each of these classes is a vitally important one, from the fact that professional service is the fundamental idea in their establishment and maintenance.

The question is often mooted whether it would not be better to have all institutions, both those established by the State and municipality and those conducted by private effort, included in one group, and all maintained by funds raised by a general tax, the whole being under properly qualified State supervision.

Viewing this question from an economic or a purely financial point of view, one might be led to acquiesce in such a proposition; but experience and reflection lead to the conclusion that such a plan would tend to destroy individual interest, effort, and responsibility, which are, so to speak, the centers from which are sent forth the altruistic motor impulses by which existing charitable efforts are initiated and maintained.

The time limit of this article is such as to forbid an extended presentation of this portion of the subject; if, therefore, it is granted that the conclusions reached are correct, it is proposed to consider briefly the character of the relation of the medical profession to the class of institutions referred to, and inquire whether such relation is fully and generally recognized by those organizing such effort, and whether among the members of the profession itself such obligations are appreciated and met.

The relation under consideration presents a twofold aspect: (1) A general or scientific, and (2) a special or individual one.

The first includes the collection and tabulation of important scientific facts and observations, and generalization thereupon; the second involves a personal service to individuals in a careful and conscientious effort to secure for them everything which may be necessary for their relief or improvement, and coresponsibility with the general management.

With few exceptions, private charitable institutions are originated and organized by persons outside of the medical profession, who become incorporators, and, later, their trustees and managers. Although such institutions may be medical or surgical in character, and dependent for continuance and success upon a medical staff, yet in a majority of instances the medical officers have no representations in the boards of trustees, and hence in the formulation of certain important parts of the policy of the institution.

It is true that this dual management, in many instances, renders acceptable service and proceeds without serious friction; yet it is evident that many of the difficulties encountered in institutions of this character have their origin in this condition of organization. This may be most easily stated by referring to the difficulties or faults which appear in a careful study of this class of institutions.

The writer has stated that the relation of the medical profession to such institutions is both a scientific and a personal one, and this becomes apparent in those cases where the medical corps constitute, so to speak, the institution. This is, however, applicable to but a small proportion of cases.

Let us start with the postulate that the primary and sole object of any institution is to provide the necessary care for its inmates, in other words, that the institution is established for the inmate and not the inmate for the institution. Is this fact kept constantly in sight in every department of its management and administration? Rarely! In far too large a number of cases the interests of the institution outweigh the claims of the inmate.

This is due to an ambition on the part of the

* Read at the meeting of the Medical Society of the State of New York, New York, October 15, 1901.

managers to build up an imposing establishment, and their pride in the institution detracts from their interest in its inmates and their care. If it be medical in character, it is sufficient for such trustees that a reputable or distinguished staff is connected with it and meets ordinary needs. Are meetings for consultation on lines of policy between boards of trustees and managers and their medical officers common or even considered essential? Again we say, rarely.

With the exception of institutions originated and organized by members of the profession, all private, charitable, eleemosynary, and correctional institutions have their origin among a small number of persons who, from sentiment and humanitarian impulses, rather than from any well-defined business policy, attempt the care of certain classes of defectives, dependents, or delinquents.

An institution is the central idea, and, as the effort proceeds, the development of the institution becomes all-absorbing.

As all such institutions require more or less medical and surgical service, the profession is called upon to render such aid gratuitously, as far as pecuniary return is concerned. It is granted that professional reputation may be gained or enhanced by such connection, but this is a consideration for the physician rendering such gratuitous service, and forms no part of the object of the originators of the institution in establishing it. Until comparatively recently, the incorporation and establishment of such institutions have been a matter of little difficulty, but their unnecessary and unwise multiplication has led to the enactment of legislation since the revision of the constitution of this State, which will materially aid the effort now being made to limit their number.

So large is the present number of private institutions for all purposes of the care of the dependent, defective, and delinquent that we are not to expect any considerable addition to this list for some time to come, and, hence, it is incumbent upon us to improve and correct existing establishments.

The medical profession, by a general effort, can do much to achieve this important result. In the seven hundred private, charitable, eleemosynary, and correctional institutions of the State are gathered about 35,000 inmates, presenting an extended field for classification and study. Herein lies the scientific relation of the profession to such institutions, and that it is by the medical officers alone that such observation, classification, and generalization can be accomplished. Is there any systematic effort to secure this valuable knowledge on the part of those connected with these institutions as medical officers, and to place it in form where it is available, not only for the medical profession, but for the students of sociology who are, at the present time, pushing eager inquiries into the causes of the existence of so many dependents, defectives, and delinquents in any community? Here and there an earnest worker appears, but such effort is individual and limited, and is rarely connected with that of others. With such a wealth of material for observation, and with a well organized and connected effort, much could be gathered and carefully analyzed. Such analysis would furnish invaluable data.

A careful inquiry into the antecedents and life-history of each inmate of our several classes of private institutions; a thorough examination as to physical and mental conditions and peculiarities; systematic records, so planned as to be easily generalized, if uniformly maintained by the medical officers of such institutions, would place at our disposal a fund of information which now largely goes to waste and is lost.

In a limited degree the State Board of Charities is able to secure some small portion of this information, but its efforts are necessarily confined to certain channels, while those specially open to the medical profession remain uncultivated. Its experience, however, leads that body to recognize the extent and importance of that field, and any systematic effort on the part of the members of the profession connected with such institutions to gain such ungathered information would receive such encouragement and aid as lie within its supervisory province.

A large number of the private charitable institutions of this State are established for the care of defective children. The relation of the physician to these institutions is, therefore, a most important one, since among these thousands of inmates we find, beside the normally developed child, the feeble-minded, the epileptic, the wayward, and those suffering with bodily infirmity of various forms. This large collection of defective humanity offers for proper classification and study an amount of material capable of returning important contributions to our knowledge. It is not the study of defective conditions and a search for their causes which are the sole demand upon the medical officer. The temporary remedial measure is not the only requirement. The abnormal condition being recognized, and its causes, possibly, being traced out, means of development and improvement, supplementary to purely medical or surgical resources are demanded. The education of the senses and perceptions is often the all-important therapeutic resort.

Recent scientific studies of cerebral function and development have demonstrated the fact that, under proper training, the cerebral centers themselves are capable of modification, and the mental and intellectual functions dependent upon the nutrition and other conditions of such centers are consequently capable of equivalent modification or development. In State and similar institutions these ideas have been put into practical form by the incorporation into the methods and systems of treatment and instruction of the inmates of institutions for the care of certain classes of defectives of such forms of developmental treatment, instruction, and teaching as shall awaken dormant mental and intellectual capacities by calling into activity cerebral areas previously inactive from lack of a proper stimulus.

In many private institutions, children are retained for considerable periods of time, and courses of instruction of some character, usually simple, are established by the managers. These consist, with few exceptions, of a limited amount of instruction in the rudimentary elements of common-school education, little reference, if any, being had, to special developmental considerations for certain cases of defectives.

In this part of the conduct of the institution the attending physician is rarely called upon to participate, yet here is met one of the most important opportunities for the application of his physiological knowledge.

The object of this article is to call attention of the profession to the responsibility of medical officers in formulating and establishing well-adjusted systems of education and training for those institutions which have for their inmates the young and adolescent, and with which they may be connected.

In our private institutions, the introduction and extension of such important factors in the education of the defective and delinquent can easily come through the medical profession. One accustomed to visit such institutions, if possessed of a medical training, soon becomes impressed with the fact that many of the so-called feeble-minded are not such in reality, but are the victims of an early environment

lacking in those elements essential for mental development which the child of more fortunate circumstances has secured.

It is the object of the writer, in this brief presentation, to call attention, first, to a vast field of observation which is now but slightly cultivated, and which, under systematic and combined effort, is capable of yielding a most valuable harvest of knowledge; and, second, to the fact that it is through the medical profession almost exclusively that this can become available. If interest in this important matter is awakened and results follow, the purpose of this article will be achieved.

NASAL OBSTRUCTION AND EAR DISEASE.

BY A. C. BARDES, M.D.,
NEW YORK.

ASSISTANT SURGEON NEW YORK EYE AND EAR INFIRMARY, THROAT DEPT. INSTRUCTOR IN NOSE AND THROAT NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

THE investigation of ear disease conducted in a scientific manner is of comparatively recent date, and careful observation and bacteriological research have placed it on the same footing as any other surgical condition. With the knowledge that the ear can be operated upon with comparative impunity, came the demand for a more thorough knowledge of its anatomy, together with its relationship to neighboring parts; this led to the discovery that the ear, throat, and nose are more intimately connected than was formerly supposed, and displaced the old idea that the ear is a distinct organ and must be treated as such.

Until recently, a person having chronic otitis, with its accompanying deafness, tinnitus, and discharge, was regarded as incurable. This was from want of knowledge respecting the true condition, the difficulty attending its treatment, and the frequent relapses. These recurrences discouraged both physician and patient, and usually led to discontinuance of treatment, when the tendency of the trouble was to become progressively worse.

We now believe that most ear troubles are secondary to an involvement of the nose or throat. It naturally follows that the careful study of the ear, nose, and throat, with their interdependence upon one another, both in health and in disease, is a necessary preliminary to the proper understanding of most affections of the ear. It is obvious that if the nasal trouble were effectively removed, the more lasting and serious disease in the ear would be prevented. Well-marked ear disease, dependent upon a nasal obstruction, rarely is permanently relieved until the nasal lesion has been cured, after which we seldom fail, even in the most chronic and seemingly intractable cases, to effect come degree of improvement.

The mucous membrane of the nose, eustachian tubes, and middle-ear is continuous, and through this channel commonly travels the disease process which precedes most ear troubles. The membrane of the middle-ear is so abundant that it lies in folds; and, like other mucous membranes, it secretes mucus which escapes into the nose.

The eustachian tube is a necessary adjunct to the ear; it ventilates the tympanic chamber and adjusts the tension of the drum; it also drains the mucus from the middle-ear and permits of the escape of superabundant sound vibrations. Though normally closed, the tubes open in swallowing and in yawning; phenomena instinctively taken advantage of whenever the air pressure in the ear is altered and needs to be equalized. When the tubes are narrowed or closed, and fail to renew the air and likewise to drain off the mucus, the middle-ear is converted into a closed space with a congested membrane, the beginning of a more serious affection.

A nasal obstruction may exert its pernicious influence upon the ear in one or more of the following ways: By the extension of a catarrhal or other inflammatory affection along the tubes, or by the actual passage of disease germs. By causing a swelling of the walls of the tubes or by obstructing their orifice. By interfering with the action of the tubal muscles, either from paresis, or thickening of the tubal membrane. By impeding the venous return from the middle-ear, or by the passage into the ear of inflammatory or septic matter by means of the blood or lymph vessels.

Ear troubles in children are mostly caused by adenoids in the nasopharynx. All children have a normal pharyngeal tonsil, which diminishes in size as the child grows older and may entirely disappear at puberty. When not enlarged, it gives rise to no symptoms whatever; but when diseased, it acts as an impediment to the various functions of the nose and ear, besides retarding the general development; the disturbance being in accordance with the size and situation of the growth.

Children are born with a healthy nose; but as their gland life is very active, and their absorbent capacity great, they are extremely susceptible to injurious influences. The growth of adenoids is favored by atmospheric changes and unhygienic surroundings; another frequent cause is the common mistake of mothers to clothe a child too warm, rendering the infant uncomfortable and making it sensitive to slight atmospheric changes. Improper feeding is another important factor in the development of adenoids; the intestinal canal becomes deranged, and the inflammation that results from the acid fermentation extends upward and becomes located in the pharynx, where the conditions are favorable for disease.

A large cushion of adenoids in the center of the pharynx may not occasion much annoyance, while small masses laterally placed may obstruct the tubes. It follows that an infant with a small pharynx may be troubled even by a small mass of adenoids, while the same amount in a child with a roomy pharynx will give rise to little or no discomfort.

Adenoids may induce ear disease in sundry ways. They may directly block the tubal opening by being forced upward by the palate in swallowing, or the inflammation that is generated by their presence may extend along the tubes, or may reach the ear by way of the blood or lymph vessels; then, again, the venous return from the middle-ear may be interrupted, and a congestion established that is injurious to the ears.

A child with adenoids presents a physiognomy that is quite characteristic, and which is due to impairment of the organs of hearing and of breathing; deafness being accountable for the child's inattention and apparent backwardness. With every cold in the head, hearing becomes worse, and attacks of ear-ache are of frequent occurrence, and in many instances terminate in discharge.

A frequent sequel to adenoids is purulent rhinitis or snuffles. During the active stage of this disease the bacteria may migrate to the ear and set up a similar affection, which terminates in discharge from the ear, often continuing unabated until the cause of the malady is cured.

Enlarged tonsils are frequently associated with, and are often indicative of, the presence of adenoids; if enlarged, they are diseased, and by virtue of their size and position interfere with the functions of the nose and ears.

In young children, the peculiar anatomical con-

struction of the nose is accountable for much ear disease. The nasal chambers and eustachian tubes form an almost continuous channel, and at the same time the pharynx is small, so that disease in the nose is readily conveyed to the ears.

While in children nasal obstruction and its accompanying evils are generally traceable to adenoids, obstruction in adults is usually caused either by hypertrophic rhinitis or its frequent associate, malformation of the nasal septum.

In this variable climate catarrhal disorders in the head are exceedingly common; besides the influence of the weather, our manner of living and of clothing has much to do with their prevalence. The impaired hearing that follows a cold is caused, not alone by thickening of the tubal membrane, but also by a venous congestion in the ear that corresponds to a similar state in the nose. Ear troubles follow nasal catarrh oftener than is generally supposed, even a moderate degree of obstruction may cause enfeebled hearing by acting as an irritant.

In chronic nasal catarrh the whole or a portion of the turbinate bodies may be so enlarged as to constitute an obstruction, causing great temporary discomfort and exerting a most depressing influence upon the sufferer. The vigorous blowing of the nose that is resorted to may injure the drum, or force septic matter into the ear. Then, again, the disease, by creating a constant tendency to clear the throat by hawking, causes the air to be sucked out of the tubes without being subsequently replaced.

A most important factor in the production of nasal obstruction is deformity of the nasal septum. Its method of development is mainly mechanical. During childhood the cartilages of the nose are soft and pliable, and their attachments incomplete, which makes the yielding septum particularly subject to distortion or dislection. When a child has a fall, or is struck in play, the blow is usually received upon the most exposed feature—the nose. In most cases the accident gives rise to no noticeable distress and the mishap is forgotten; the consequence is that nature throws out a mass of callus along the line of injury and forms a spur or a ridge; if the septum does not return to its original position, a dislection may result, which, as the child grows older, correspondingly increases in size. An enlarged turbinate by pressing upon the yielding septum may cause it to be dislected, or it may assist in the formation of a spur. A pronounced septal dislection or a large spur will obstruct breathing and prevent the entrance of air into the ear, while a slight dislection or a small spur might effect the ear indirectly by irritating and congesting the nasal membrane.

Enlargement of the posterior part or tip of the turbinate is frequently met in connection with ear disease, and commonly overlooked by physicians because of its obscure situation in the post-nasal space. Because of its size and position it often obstructs the nose and the mouth of the tube, which is directly behind it. These growths give much annoyance at night; first, one side of the nose and then the other being occluded.

Atrophic rhinitis, or dry catarrh, is another malady that is the forerunner of ear disease. Residue is deposited about the mouth of the tubes, which acts both as an irritant and as an obstruction. The disease may also spread and induce a like affection in the ear. Dry catarrh is the outcome of an uncured purulent rhinitis, which destroys the delicate nasal membrane. Nature replaces this with a glandless structure which becomes the seat of a dry catarrh. The forcible blowing to dislodge the crusts may injure the drum, or force foreign matter into the ear.

Enlarged middle turbinals, sinus disease, polyps, and other forms of nasal trouble may be injurious to the ears, either by acting as obstructants, or by causing disease of the nasal membrane. In hospitals, we treat many ear complaints induced by the use of the nasal douche. The fluid enters the nose under pressure and is unable to escape past the swollen membrane; it becomes confined in the postnasal space, and soon makes its way to the ear often carrying with it pathogenic organisms. If the nasal chambers are not perfectly clear, or if ear trouble be present, it is safer to use an atomizer than a douche; for while the spray does not cleanse the nostrils so well, its use is unattended with danger to the ears.

The promiscuous use of nasal sprays, douches, and washes is to be deprecated, they irritate and inflame the delicate nasal membrane.

The eustachian tubes may be abnormally closed and their acting impeded by cicatricial bands which follow the healing of diphtheritic, syphilitic, or other ulcers in the vicinity of the tubes, or by the misuse of instruments. Then, again, they may be forcibly opened and permit the entrance of septic matter. This, in a measure, accounts for the frequency with which purulent otitis follows such infectious diseases as typhoid fever, scarlet fever, diphtheria, etc. In tuberculosis the first tissue in the body that is consumed is fat; the cushion of it that surrounds the mouth of each eustachian tube slowly wastes away and leaves a large aperture through which tubercle bacilli and other organisms may migrate to the ears, producing a peculiar painless suppuration which destroys the drum and escapes.

In the middle-ear as in all vascular spaces the volume of air is diminished whenever free communication with the external atmosphere is interrupted, and this occurs whenever the eustachian tubes are obstructed. The oxygen in the air enters into chemical combination with the blood in the membrane of the middle-ear and the amount of CO_2 given off to the blood is insufficient to compensate for the loss of volume in air; thus the air is slowly absorbed and the pressure in the middle-ear is reduced, leading to congestion of the membrane and derangement of the delicate structures that constitute the organs of hearing. With the dilatation of the vessels comes transudation of serum, which furnishes a good culture medium for the multiplication of bacteria. If the eustachian tube is open, the serum will escape from the ear, and the condition will not get beyond the catarrhal stage. If, however, the fluid is confined, an abscess may result which usually ruptures the drum and escapes. The after effect of an abscess may be short or long, and healing of the perforation in the drum may take place only to reopen with the next cold in the head, until finally the condition lapses into a chronic discharge.

A moderate degree of tubal obstruction may lead to partial strangulation of the veins and lymphatics that pass from the middle-ear to the nose; or it may assist in the spread of the catarrhal disease. In either case, the pressure in the middle-ear is diminished and the free exchange of air interrupted. The drum is retracted, and the ossicles displaced in proportion as the air pressure is lowered and the tubes obstructed.

After an attack of scarlet fever, diphtheria, or other infectious disease, the mucous membrane in the various cavities in the head secretes very actively. The mucus from the middle-ear is drained off by the tube if the amount is not too large and the tube is open. If the tube is obstructed, the mucus accumulates in the ear, and finally, by its pressure, bursts through the drum and escapes. No effort should be made to close this opening in the drum until the active discharge has ceased, or else the fluid will collect and

become purulent. The pressure of confined pus in the middle-ear is often intense, and unless it receives vent through the drum, it will extend into the interior of the bone and possibly invade the brain. That the latter course is a common one is proved by statistics, which show that most brain abscesses have their origin in the ear; lack of drainage having forced the confined pus to seek an avenue of escape at the place of least resistance, which in these cases is in the brain cavity.

Treatment.—In the cure of disease, removal of the cause is the first principle. In the intelligent treatment of ear disease, we must first seek the conditions that have led up to the disorder and eliminate them as far as possible, for only on such procedure can we base our conclusions and formulate a line of treatment. One reason for failure to cure ear disease is neglect to remove the cause. This is so generally recognized by modern specialists that instead of treating the diseased ear at once, the nose and throat are first put in order; that done, in many instances the ear trouble will subside without further attention.

In former years, children with running ears and deafness received very little medical attention because of the unsatisfactory results attending treatment. Usually, mothers were quieted with the statement that the infant would outgrow the affection; this, however, is seldom the case, for these ailments rarely improve without treatment.

The advantages attending the removal of nasal obstructions have been so apparent that the correction of the same is warranted if any other condition is present that is likely to be influenced by it. The benefits obtained by securing permanent openings in the nasal passages are manifold; the results are partly derived by the relief of the catarrh, congestion, and partly from the better supply of air.

The restoration of a diseased ear is brought about in one of the following ways. Removal of cause, cleanliness of the parts, astringents, and constitutional treatment. The first object, then, is to put the nose and throat in a healthy state. This is generally attained by medicinal and surgical means aided by the judicious use of cocaine and suprarenal extract.

Those cases of ear disease that are benefited by tubal inflation are usually assisted by a nasal operation; in the others the infirmity is certainly retarded, and increasing deafness prevented.

In conjunction with local treatment, internal medication is often desirable. The patient should likewise receive advice respecting food, clothing, baths, and other hygienic measures, in order to resist the harmful influences of atmospheric changes which conduce to the development of most ear troubles.

317 East Thirteenth Street.

BUTYRIC AND ACETIC ACIDS IN THE CONTENTS OF THE STOMACH AND TESTS FOR THEIR DETECTION.

By MARK I. KNAPP, M.D.
NEW YORK
ATTENDING PHYSICIAN, OUT-DEPARTMENT, AUSTRO-HUNGARIAN HOSPITAL; DEPARTMENT OF DISEASES OF THE STOMACH.

Butyric and acetic acids are known to be present in the contents of the stomach under certain conditions. But the detection of these acids involves a procedure not very eagerly nor pleasantly undertaken. The reason for this is very obvious, as the method given is very cumbersome. It also requires skill in chemistry, and its technique requires apparatus and time, and, if but a little quantity of chyme is at our disposal, only a very skilled chemist might discover it. And yet the knowledge of its presence is of very great importance. Of so much importance, indeed, is this knowledge that more than once did it transform a diagnosis of a "nervous, functional disorder of the stomach" into a disease, having a more "tangible, substantial" cause, which was quickly and easily cured. How often does one read of the diagnosis of hyperchlorhydria, made and based solely and only upon the depth of the blue color of the congo paper; nay, not even taking the trouble to substantiate this by titration! We read it, and while abroad I have seen it done by authorities. It is just the very deep blue color of the congo paper that ought at once to make one suspicious, no matter how high or how low the free acidity has been found to be. If one observes this blue tinge more scrutinizingly, he will note that this blue merges into a grayish hue. This grayish-blue color has so far proven to me to indicate the presence of other free acids besides HCl, and only recently have I been fortunate to demonstrate the identity of some of these acids—butyric and acetic acids. How many cases, reported in literature as hyperchlorhydria and based upon the usual method of titration, have been real cases of hyperchlorhydria instead of cases of *oxyacidita gastrica*? I want to introduce this last term as a condition of the stomach, a disease due to the presence in the stomach of large quantities of organic acids. Fermentative gastritis is used to designate such a condition, but there is objection to that term. First, organic acids may be present without being the product of fermentation, or causing fermentation, and secondly, fermentation does not necessarily at once produce a gastritis. I have quite often seen fermentation without gastritis, and undoubtedly other observers have had the same experience. Furthermore, gastritis produces definite and distinct symptoms, which I shall describe in a subsequent article. I should like to state here (parenthesis) that I have [illegible] not to base upon the term of hyperchlorhydria, hyperacidity, and organic acidosis symptoms. These terms represent conditions caused by distinctly different agencies. They are overall, and inclusive, distinct from one another, which I shall soon add, gastritis. Thus, we see that the [illegible] of butyric acid and of acetic acid is a very great value for [illegible] of even greater importance [illegible] lactic acid, which latter [illegible] in the initial stages of digestion.

Of very great importance will certainly be the valuable discovery I fortunately made of the behavior of butyric acid, and of the monocalcium phosphate upon congo paper and upon the dimethylamidoazobenzol. Butyric acid, neither dilute nor concentrated, reacts on congo but does not react on dimethylamidoazobenzol. Monocalcium phosphate reacts on both—congo and dimethylamidoazobenzol. Monopotassium phosphate and the monosodium phosphate do not so react. In the light of this discovery, how much can be relied upon all the literature bearing on the question of hyperchlorhydria? One involuntarily shrinks back from thinking of it.

Butyric and acetic acids are products of fermentation, and their presence in the gastric contents, unless introduced as such, means fermentation, hence the very great importance of their detection. The present method to prove the presence of these acids in the chyme is by the very cumbersome process of distillation. No other method is mentioned in the latest editions of Hammarsten, Neumeister, Riegel, and others. Distillation is criticised above, and is certainly not an elective method.

The test which I am to describe now is very simple. It requires only one glass apparatus, a separatory funnel, and but a few minutes' time to execute. The

reagents necessary are. A 10-per-cent. solution of ferric perchloride and ether. This test is made in the same way as described in my test for lactic acid (*New York Medical Journal*, August 10, 1901), only the color of the ring at the line of junction, between the ether and the iron solution, differs—the color of the ring in the lactic-acid test is sulphur-yellow, the color of the ring in butyric acid is a reddish-orange color. The mode of procedure is the following:

One c.c. of the filtered gastric contents is extracted with about 5 c.c. of ether in a glass separatory funnel. The ether with the filtered chyme is shaken up a few times, and then allowed to stand for a short while to allow the ether to separate from the underlying stratum. In the meanwhile, a solution of the iron is made in the following way: One drop of a 10-per-cent. solution of iron perchloride is dropped into 2 c.c. of distilled water in a narrow test tube. Now, the lower stratum in the separatory funnel is allowed to escape by opening the stop-cock and the remaining clear ether extract is floated on the clear iron solution. At the line of junction of the two clear fluids an orange-colored ring appears if it is butyric acid, and a rather rusty-colored ring if it is acetic acid. A few drops of alcohol will increase the intensity of the color of the ring. To differentiate between the two—butyric and acetic—acids, a little more alcohol is added, the finger placed on the test tube, and the test tube shaken a few times by inverting it. If it is butyric acid, the ether layer will be colored a beautiful orange; but if it is acetic acid, the ether layer remains clear. Acetone and aldehyde respond to the same method of testing, but the color of the ring formed is different. Acetone and aldehyde give a light ochre-yellow color, shading somewhat into a light green. The ring in aldehyde is very distinct, the line between it and the ether being very sharp, looking almost black; acetone gives the same color, but is not so distinctly and sharply marked off. A sheet of white paper held back of the test tube, our back turned to the source of light, will make us better appreciate the colors.

In the following experiments I floated on the iron solution mentioned above butyric acid in varying strengths, and for comparison used, once, lactic acid:

1. 1 drop lactic acid in 5 c.c. ether, beautiful sulphur-yellow ring.
2. 1 drop butyric acid in 5 c.c. ether, no reaction.
3. 5 drops butyric acid in 5 c.c. ether, no reaction
4. 10 drops butyric acid in 5 c.c. ether, no reaction.
5. 20 drops butyric acid in 5 c.c. ether, no reaction.
6. 30 drops butyric acid in 5 c.c. ether, no reaction.
7. 50 drops butyric acid in 5 c.c. ether, faint reaction.

However, after the test tube (3) had stood for over two hours, the characteristic color appeared. A mixture of one drop of lactic acid, plus 15 drops of butyric acid, gave the sulphur-yellow ring only. One drop of lactic acid plus 40 drops of butyric acid plus ether up to 5 c.c., shaken up together and floated on the iron solution, gave the sulphur-yellow ring only.

These experiments show that it requires quite a large quantity of butyric acid to give its reaction, consequently that, when the reaction is positive, a considerable quantity may at once be suspected. Of course, it may yet be demonstrated that other agencies present, together with butyric acid, may enhance the reaction for the butyric acid, but this has yet to be demonstrated.

For the following experiments the following solutions were used:

"A," 1 c.c. glacial acetic acid plus 4 c.c. ether.
"B," 1 c.c. butyric acid plus 4 c.c. ether.
"L," 1 c.c. lactic acid plus 4 c.c. ether.

In the performing of the tests a little less than 1 c.c. of the solutions "A", "B," "L" were floated on the iron solution mentioned above. If, instead of but one drop of the 10-per-cent. iron solution, two or three drops were added to the distilled water, the reaction was more pronounced. I prefer, however, but one drop of the iron solution, because then the solution is practically colorless.

"A," floated on the iron solution, gave an orange ring. When 0.4 c.c. alcohol (95 per cent.) was added and the test tube shaken, the ether column diminished in height, but remained perfectly clear; the iron solution did not change its color. On the further addition of alcohol (from a 1 c.c. pipette, graduated to measure $\frac{1}{10}$ c.c.) and the shaking of the test tube, the ether column kept on diminishing in height, and the lower iron solution became lighter in color. When the alcohol was added up to 1 c.c., the ether column disappeared entirely, and the test tube then presented one homogeneous, light-orange, clear solution. The orange color was best seen when looking down on the surface of the solution.

"B," floated on the iron solution, showed a narrow orange ring which became much more distinct on the addition of 0.5 c.c. alcohol. Now, shaking the test tube, the ether column was colored a beautiful orange. On the further addition of alcohol up to 1 c.c. and shaking the test tube, the ether column disappeared entirely, and a slight cloudy ring could be seen midway. After standing for a little while, the entire solution became faintly milky.

"B," floated on the iron solution, and the test tube shaken, without the addition of alcohol, the ether column became milky and the iron solution a somewhat deeper color. Without the addition of the alcohol the ether column did not become orange colored.

About 1 c.c. of a mixture of equal parts of "A" and "B" was floated on the iron solution. Two rings appeared: A narrow colorless ring, rather faintly milky, immediately below the ether column, and below this the orange ring.

About 1 c.c. of a mixture of equal parts of "A" and "L" was floated on the iron solution. The result was a reddish orange ring immediately below the ether column, and below this a sulphur-yellow ring. On shaking the test tube, the sulphur-yellow ring disappeared, the ether column remained colorless, and the iron solution got the acetic-acid reaction, *i. e.* faint rusty red. The addition of alcohol did not change this reaction.

About 1 c.c. of a mixture of equal parts of "B" and "L" was floated on the iron solution. The result was a sulphur-yellow ring. On shaking, however, the sulphur-yellow color diffused in the iron solution, and the ether column became milky. On the addition of 0.4 c.c. alcohol and shaking the test tube, the lower column got lighter in color and the ether column became orange colored.

About 1 c.c. of a mixture of equal parts of "A," "B," and "L" was floated on the iron solution. Two rings appeared. A pronounced orange ring immediately below the ether column, and below this a sulphur-yellow ring. On shaking, the iron solution got the color of olive oil—a greenish yellow—but the orange ring remained. The addition of 0.4 c.c. alcohol increased the intensity of the orange color. On shaking the test tube, the iron solution got a light amber color and the ether column remained clear.

The ether extracts of acetone and aldehyde were floated on the iron solution. Each gave a light, ochre-yellow ring. But the ring of the aldehyde was much more sharply marked off from the supernatant ether extract, and its color ran into a shade of sulphur yellow, although the ochre yellow predomi-

nated. I have not yet been able to find more exact means of differentiation between aldehyde and acetone, unless it be the different odor of each. Aldehyde gives a rather sweet odor, while the odor of acetone resembles that of chloroform.

In concluding, I will give two illustrations—one of organacidia and one of hyperacidity. Both of these cases presented symptoms that go with these conditions of the stomach, and which symptoms are heretofore interpreted as diagnostic of a "functional gastric disorder," as a "neurosis of the stomach," as "nervous dyspepsia," etc. The first case was one that would ordinarily go as a case of hyperchlorhydria. It gave a general acidity of 120 and free acids 80, just double of the maximum normal limit. My test for butyric acid was positive, lactic acid was absent. (At the time of making this test, I had not yet known the tests for acetic acid, nor for aldehyde, nor for acetone, nor did I know of the behavior of the monobasic calcium phosphate.) The filtered, gastric contents were extracted with ether in a large pear-shaped separatory funnel. The lower part in the funnel, the chyme, was then run into a beaker and left standing for some time, in order to permit the ether, which was still in the chyme, fully to evaporate. Now, this ether-extracted chyme was again titrated (dimethylamidoazobenzol for free acids and phenol-phthalein for the general acidity). This titration gave general acidity 76 and free acids 48. I must admit here, that I have not attempted to go to the full limit of the ether extraction, as it would have required much more ether. I was satisfied with the result obtained, and put this case down as one of "organacidia."

The other case was also one, usually pushed into the category of "idiosyncrasy," "nervousness," "hysteria," "neurasthenia," and had a general acidity of 56, while the free acids gave the value of but 10. What a disparity between the two values! There was no lactic, nor butyric, nor acetic acid present in this case, but there were present alcohol, aldehyde, and possibly some acetone. This case I consider as a case of hyperacidity—the presence of a low value for the free acids associated with the maximum normal limit of the general acidity.

I might add, in conclusion, that I doubt very much if an excess of hydrochloric acid—if such be proven beyond any doubt—*per se*, ever gives any symptoms at all. From my past experience with a great number of such cases, I came to the conclusion that the symptoms of *organacidia gastrica*, which, as mentioned above, I shall describe in a subsequent article, are due to the presence of the volatile organic acids. The symptoms of hyperacidity are due to the presence of acid combinations together with volatile media, such as alcohol, aldehyde, and acetone.

All the chemicals used in these experiments should be chemically pure.

136 East Seventy-fighth Street.

Fever; a Symptom.—Hedley Williamson believes that it is the bacteriologist who will finally give us accurate knowledge of this subject. Fever is both a normal and a pathologic function. It would be bad for the patient if his temperature did not rise during the course of a disease. The writer believes that a reduction of temperature interferes with the course of the disease. In cases of smallpox, where he has kept the temperature very low, the length of time of the eruption was greatly increased. As to the bath treatment of typhoid, although he admits its beneficial results, he looks forward to the discovery of some remedy which is directly antagonistic to the development of the bacilli causing the intestinal abscesses. He anticipates the discovery of something antagonistic to the development of disease.—*The Physician and Surgeon.*

GANGRENE FOLLOWING THE USE OF CARBOLIC ACID.

By JOHN GLENDON SHELDON M.D.,
TELLURIDE, COLORADO
SURGEON IN-CHIEF OF THE MONTROSE HOSPITAL; CONSULTING SURGEON TO THE TELLURIDE HOSPITAL

James W., coachman, aged thirty-seven, colored, came to Cook County Hospital March 11, 1901 complaining that his left foot was "cold and dead," and that it was very painful. Eight days previous to entering the hospital, he noticed a "sore" on one of his right toes. He consulted his employer, who was a physician, and was given a dilute solution of carbolic acid with instructions to use it on the affected member. While preparing to follow directions, he accidentally spilled some of the carbolic solution on his left foot. This frightened him, and he neglected to apply any of the medicine to his right foot, which he had intended to treat. All went well for five days, and then the left foot began to feel "numb." The numbness increased; and, on the seventh and eighth days, the foot had become "dead and painful."

Examination showed a well-developed, well-nourished adult of medium size. The left toes and foot—as far as the mediotarsal joint—presented the appearance of dry gangrene. The tissues, about the ankle, were swollen and œdematous and showed beginning gangrene in places. No definite line of demarkation could be made out. The remainder of the examination was negative. Pulse 100, temperature 99.8° F., respiration 19. The heart and blood vessels were normal. Uranalysis was negative, no sugar and no albumin being found after repeated examinations. There was no evidence of syphilis, no glandular enlargements. The lungs, liver, and spleen were normal; as were also the reflexes, eyes, and nervous system. The patient had malaria ten years ago; but had suffered from no other sickness. He denied having had any venereal diseases. The family history was negative, and the man denied the possibility of intoxication from chemicals or food materials.

Amputation was done at the middle of the leg. The fatty tissue at the site of the incision seemed œdematous and slightly more yellow than normal, otherwise the tissues appeared healthy. It was noticed, however, that after the larger vessels had been tied, and the constrictor removed, no bleeding occurred from the stump. The wound did not suppurate, but the patient's pulse remained rapid and his temperature varied from 99° to 102° F. The gangrene extended, being now of the moist type, and in two days reached the knee. Sixty hours after the first operation was performed, a second amputation was done at the junction of the middle with the upper third of the thigh. The wound healed rapidly, except the opening made for drainage, which discharged pus, containing staphylococci, for about ten days. The temperature and pulse gradually became normal, the pain disappeared, and the patient made a rapid and uneventful recovery.

The stump from the first amputation was lost, and no examinations of it were made. Slides and cultures made from the incision of the second amputation gave negative results. Examination of the amputated stump showed no gas in the tissues. The soft parts were moist, œdematous, and discolored, no pus was found, and no definite line of demarkation was made out. The vessels and nerves appeared normal above the site of the gangrene. Slides from the gangrenous parts showed no organisms except a small straight bacillus, which had no characteristic arrangement, and which stained with the ordinary stains and decolorized with Gram's method. The bacillus grew rapidly on the ordinary media—white

circular colonies on agar—but ceased to grow after four or five days, and seemed to die in about a week. No motility could be observed. Two cubic centimeters of twenty-four and forty-eight hour bouillon cultures injected into the subcutaneous tissue of guinea-pigs gave negative results, except for a slight swelling at the site of injection which disappeared in three or four days.

Cases of gangrene following the local use of carbolic acid, though not common, are reported frequently enough, and are of sufficient gravity to warn the surgeon of the danger of using the drug, especially in cases in which the acid is applied in such a manner that evaporation is impossible. Harrington (*American Journal of the Medical Sciences*, June, 1900) reports having found records of one-hundred and thirty-two cases. In eighteen of these the lesions were grave enough to require amputation. The others varied in severity from slight necrosis of the skin to extensive losses of tissue.

The explanation of the occurrence of carbolic-acid gangrene cannot at present be satisfactorily given. It is not known why gangrene should occur in one case, and no injury to tissue take place in another individual treated in an identical manner. It is probable that the idiosyncrasy of the patient and the surrounding conditions play an important part in each case. It has been noted, however, that gangrene is more apt to occur in cases in which the acid is applied in such a manner that it cannot evaporate quickly. Also, that while gangrene may follow the use of any strength of solution, it occurs more often in cases in which dilute solutions are applied. Levi's explanation for this is that the strong solutions produce an eschar at the site of application, which prevents further absorption of the acid. This explanation is not entirely satisfactory. Carbolic acid has the same action on albumin as has alcohol. The tissues are not precipitated, but are rendered insoluble and the drug continues to be absorbed through the eschar.

Another point, on which there is some difference of opinion, is the primary pathological change—in the parts affected—on which the gangrene depends. Carbolic acid is a general protoplasm poison, and it would seem probable that the gangrene is due to the direct destruction of all the tissues acted upon by it. This is Levi's theory. He does not see why any chemical, such as nitric acid, might not produce gangrene in the same way. The action of the carbolic acid is not the same as is that of most other escharotics. Nitric acid, the example quoted, is a protoplasm poison, but it precipitates the proteids, forming a firm coagulum. It also has a special affinity for globulins. Not all authors agree that gangrene is due to all of the tissues being equally affected. Frankenburger, from his experiments on animals in 1890, believes that the gangrene is due to the action of the carbolic acid on the blood vessels producing blood stasis and anæmic necrosis of the parts involved. Krotum believes that the gangrene results from some specific action of the acid on the nerves. Nothing was found, in examining the specimen from the case I treated, to indicate that the nerves or arteries were more affected than were the other tissues in the gangrenous part. In fact, the nerves seemed less affected than did any other soft tissue. The clinical history of the case herewith reported favors the theory that the gangrene is due to the direct destruction of all of the tissues brought in contact with the acid. No cases are reported in which the gangrene was limited to the distribution of an artery or a nerve.

There is one point in the clinical history of cases of carbolic-acid gangrene about which I wish to say a few words. I refer to the spreading of the gangrene. It is stated that the gangrene comes on in about ten or twelve hours, and Levi says that it is limited to the area brought in contact with the acid. If the gangrene, in the case herewith reported, was due to carbolic acid—and I can see no other reasonable explanation for it—Levi's statement no longer holds good. But it does not seem possible to me that such extensive progressive gangrene could result from the application of so small an amount of carbolic acid. But I have nothing better to offer—no infection atrium, no sufficiently virulent organism, and no general condition—to explain the loss of the limb.

In the treatment of carbolic-acid gangrene, prophylaxis is most important. However, if the acid is used, it should never be applied unless the conditions for its evaporation are suitable. When gangrene has occurred, the treatment, of course, depends on the amount of tissue destroyed. Porter saved a finger by skin grafting. Amputation has been resorted to in eighteen cases besides the one I report. Radical measures must be employed if progressive and spreading cases are found to occur.

FOOD AS AN ETIOLOGICAL FACTOR IN DISEASE.

By GEORGIA MERRIMAN, M.D.

BUCYRUS, OHIO.

Ever since the original episode of eating "forbidden fruit" in the Garden of Eden, man has been troubled by what he ate; thus giving the patent-medicine man, proprietary pharmacies, and quacks the field of stomach and kidney specialists.

Is it not time that the whole medical fraternity, from center to circumference, attempt to recover the legitimate ground by scientific investigations along these lines of inquiry?

If the amount of strength, heat, and power, mental or physical, to be developed from a certain amount of food can be measured in the chemical laboratory, may not the dosage for food become as exact as the dosage for medicine?

Correct dietaries for the brainworker, the manual laborer, and the average citizen in good health have been accurately estimated by the scientific experts in government employ; but the perfectly adjusted diet for patients afflicted with gout, rheumatism, and allied diseases, caused by retention in the system of alloxuric bodies, intended to be either dissolved or eliminated, is still unknown to the average practitioner. One forbids the use of beef, cheese, and eggs, because of the xanthin and hyperxanthin developed in their metabolism; while another forbids all food which produces nucleo-proteids, or purin-nitrogen, and a still larger proportion permit all kinds of food to be ingested, depending upon drugs to aid in their rapid elimination.

The trend of hygienic thought to-day is toward preventive remedies. The etiological germ is fast disappearing under an antiseptic therapy, the laity have resorted to patent and secret remedies, and the general practitioner continues his old humdrum practice founded upon theories long since exploded.

Is not this the opportune moment for the physiological chemist to furnish some reliable data upon which each physician may construct a suitable diet for each patient, or groups of patients, if he have enough to group them? All honor to original investigators like Röhmann, Haig, Kossel, Salomon, Horbaczewski, Flatow, and others; but is not the dearth of general conclusions most manifest?

Is it wise to allow rheumatic patients or those suffering from uric-acid diathesis to continue consuming food which will certainly increase the amount

of colloid urates, while you are concentrating all your efforts upon their elimination? In other words, is it not reprehensible for any doctor to be ignorant of the preventative methods of treatment as well as the eliminative? The list of diseases caused by the continued use of indigestible foods is increasing daily. Some of the most-learned nasal and throat specialists are now advocating the theory that certain forms of nitrogen are present in lithæmia, gout, migraine, acute coryza, la grippe, and many, if not all, neuralgias. But as expressed by another:* "The average medical man clings to an old idea in pathology or treatment with a tenacity that blinds his eyes and deadens his ears to the heralding of a new theory, though born to point the way to the living truth, and if, perchance, it demolishes the images of a blind idolatry, lucky indeed is it if the very truth be not sacrificed upon the altar of conservatism, or crucified upon the cross of unbelief.

The point I wish to make is this, that in my opinion the time is ripe for an entire revolution in the administration of drugs. The proper digestion and the proper ingestion of food constitute the most successful field of therapy now known to man.

Then, why should not every well-informed physician write a prescription for food, which would exclude the articles of diet known to cause the conditions producing the disease he is trying to cure? I have found a *written dietary* almost indispensable in securing a change of food, and oftentimes order the exact quantities to be taken.

The fact that albumin from animal foods leaves a larger percentage of uric acid than albumin from vegetable sources need not necessarily make vegetarians of all, even though it does behoove those suffering from indigestible xanthin bodies to restrict their use of animal nitrogenous combines. The field of inquiry, in this direction, is so fertile that post-graduate courses in dietaries for every disease would be a boon to mankind.

Individual experimentation is slow and inaccurate. In the accurate Government experiments, under the direction of Professor O. A. Atwater, it was found that dietary idiosyncrasies played no essential part in the perfect nutrition of man as to quantitative analyses, but the digestive powers varied with the individual. Have we not overlooked this fact in trusting blindly to the use of drugs in latter-day therapeutics? The powerful alterative effect of medicine was highly esteemed by the old-time practitioner. Do we not seek the same end by alkaline treatment to-day? In my specialty of stomach diseases I have found that other diseases disappear under the wisely chosen diet and exact régime necessary to supplement the proper administration of drugs for the diseased organ. An exhibition of alkalies, such as sodium bicarbonate combined in tablet form with oil of gaultheria, is followed by decided relief of all symptoms of rheumatism, gout, acute coryza, la grippe, and asthma; and the general improvement continues if the diet is restricted to zwieback, or well-cooked, that is, twice cooked, wheat, barley, or oats, with nuts finely divided, and green watery vegetables. All bread, potato, and uncooked starch cells are excluded. Fruits and salads are used ad libitum. Dr. Conklin's ideas of the uses of fats in the system are sustained by results from their administration, and a logical sequence from his premise might be that the larger percentage of nitrogenous material, combined by nature with so great a proportion of fat, aids in the more perfect metabolism of the alloxuric bodies, thus rendering nut foods safer than an excess of meat or egg.

*Dr. A. B. Conklin.

What Regulations Are Most Advisable for the Control of Prostitution.—Felix Block says that most important of all is the elevation of the intellectual and ethical level of the people at large, together with the inculcation of respect for women on the part of the growing youth, the instruction of all ranks of society regarding the dangers of sexual diseases, and the better schooling of physicians in their treatment. These measures will work slowly, but will ultimately effect much more than any legal restrictions, though these, too, must be brought to bear on the question. The great disadvantage of most systems of legislation now in vogue is that they tend to restrict open prostitution, which could be kept under supervision, with comparative ease, by strict regulations, which serve only to scatter the evil and foster clandestine prostitution, which it is wholly impossible to control. Medical supervision should be made less of a police regulation and more in the nature of clinical treatment. All prostitutes regular in reporting themselves for examination at stated, say, biweekly, periods should be allowed to carry on their occupation unmolested, while others detected in evading the law should be stringently dealt with. The invasion of the homes of the poor by this class is particularly harmful, as tending to deprave the growing generation; but this is precisely what the attempt to rule fallen women off the streets results in. Men also should be kept under some sort of control, and it should be a penal offense for any one to have intercourse while suffering from a venereal disease in the infectious stage.—*Volkmann's klinische Vorträge.*

Pendulous Tubercles in the Peritoneum.—W. G. MacCallum reports the case of a white woman, aged thirty-eight, who died with symptoms of pulmonary tuberculosis. Autopsy revealed in the peritoneal cavity nodules lying just under the serous surface, over both parietal and visceral layers. They varied in size from 1 or 2 mm. to 2 cm. in diameter. Some were sessile and flattened, but most of them hung free, and were inclosed in a long blind tube. Some of the pedicles were from 10 to 12 cm. long. They all contained fluid. In one or two cases the tubular prolongations showed no caseous mass at the end. The intestinal mucosa was nearly normal. The abdominal lymph glands were apparently uninvolved, though the cervical and mediastinal lymph glands were almost entirely caseous. The spleen and liver were adherent to adjacent tissues by old adhesions containing caseous masses. The lungs were adherent to the costal pleura. There was a tuberculous leptomeningitis. The nodules in the liver, spleen, and lungs showed all the histological features of tubercles. Tubercle bacilli were numerous in the peritoneal nodules. Dr. Welch suggests that the tubercle masses were formed, in part at least, in preëxistent loose adhesions and strands of vascular new-formed connective tissue, accepting at the same time the importance of gravity when the mass had grown to some size.—*Bulletin of the Johns Hopkins Hospital.*

Curetting the Uterus in Out-Patient Clinics.—F. B. Bucoemsky describes his experience in curetting the uterus in dispensary practice. His method is as follows: In recent cases of abortion, the operation is performed immediately after the arrival of the patient at the clinic, but in cases of endometritis, a strip of iodoform gauze is introduced into the uterus, and the operation is performed the next day. Both before tamponing and before curetting, the vagina, cervix, external genitals, upper portion of the thighs, and lower half of the abdomen are flushed for three minutes with tincture of green soap and a hot solution of formalin (1 to 500). After curetting, the uterus is washed out with the same hot formalin solution (3 to 4 quarts), and about 30 grains of solution of iodine is injected into the uterus, and, after the escape of this, the vagina only is packed with a feebly iodoformed strip of gauze, as it is not advisable to interfere with the con-

traction of the uterus, besides, the tamponing often causes great pains, and drainage of the uterus is necessary only in cases of infection. After curetting, the patient is removed to the bed, 0.5 to 1.0 ergot powder administered, and an ice bag placed over the lower half of the abdomen. Thus she remains resting for three hours, after which she rides home with the instructions to remain in bed for three or four days, and at the expiration of this time to present herself at the dispensary for examination. This the patient always does.—*Vratch.*

Some Aural Complications of Influenza.—S. MacCuen Smith says that hemorrhagic otitis is by many believed to be *the* distinguishing feature of otitic influenza. Mastoid implication or irritation is present in all severe cases. Meningitis, lateral sinus, thrombosis, intracranial and extradural abscesses are encountered more frequently with each succeeding epidemic. The virulence of an aural discharge cannot be judged by its odor, nor can the gravity of an otorrhœa be measured by its chronicity. An odorless discharge from the ear sometimes contains pathogenic micrococci, which may cause some of the most serious intracranial inflammatory lesions. Treatment must be prompt and energetic. Absolute rest in bed, free diuresis, and properly conducted diaphoresis are of the first importance. The external layer of the membrane tympani is composed of modified skin, and is influenced but little, if any, by medicated solutions. Solutions of cocaine, belladonna, etc., cannot be depended on to relieve pain, except from the caloric they impart. Blood-letting in front of the tragus is of service, but must be used at the beginning of the attack. Early incision of the membrane is the best conservative.—*Pennsylvania Medical Journal.*

A New Method of Treatment of Cancrum Oris.—A. A. Kiecl arrives at the following conclusions. (1) Noma in children may terminate in recovery in a large percentage of cases. (2) Curetting with sharp curette and subsequent washing of the ulcer with hot solution of potassium permanganate and rubbing in with iodoform powder greatly increase the chances of a favorable termination of the disease; (3) Energetic and persistent treatment must begin from the very first day of the disease, and at the arrival of such a patient at the hospital all the measures above mentioned must be taken at once; (4) The food must be very nutritious, and the hygienic conditions the best possible; (5) Regarding preventive measures, special care must be given to the food of those suffering from measles, and to the cleanliness of their oral cavity, especially when caries of the teeth is present; (6) Sometimes the disease assumes an endemic character; (7) Cases of noma vary greatly in intensity; (8) Sometimes in noma the gangrenous process ceases spontaneously; (9) In the majority of cases the disfigurement of the face after cicatrization is comparatively slight.—*Khyrurgia.*

Chappa.—Edward H. Read reports four cases of a disease which he has not seen described in any textbook, but which is called "chappa" by the Popo people in the western district of the colony of Lagos. It begins with severe pains in limbs, muscles, and joints, which after a few months decrease and give way to swelling. At the same time, nodules develop in different parts of the body, which, without abscess formation, are exposed by ulceration of the skin over them. They are usually multiple, are circular or oval in shape, with a fatty-looking base, and about the size of a pigeon's egg. The nodules are sometimes absorbed without proceeding to ulceration. The disease, after a time, attacks the bones, and the joints may become totally disorganized. The author believes that the disease is neither tuberculous nor syphilitic. Various forms of treatment have been tried with doubtful success.—*The Journal of Tropical Medicine.*

The Outdoor Treatment of Sick People. George H. Carvette would place patients in the open air all the time, rain or shine, hot or cold, day or night, summer or winter, properly protected against changes in the weather, and having a trained nurse within call to put on or take off clothing as required. This plan can be carried out on a lawn, under the trees, on a veranda, or in a properly constructed tent. Patients suitable for this treatment are those suffering from debility, bronchitis, rheumatism, accidents, insanity, alcoholism, measles, diphtheria, Bright's disease, severe operations, pneumonia, typhoid fever, tuberculosis, and many other troubles. According to the writer's experience, cases of illness recover in about two-thirds of the time required under the old plan of treatment; the more healthy appearance of the patient under the influence of the wind and sun has an encouraging influence on the friends and visitors, and their remarks on this point again add hope and encouragement to the patient. In operation cases of all kinds there is less sickness after anæsthesia, and the time of recovery is shorter and pleasanter.—*Canadian Journal of Medicine and Surgery.*

The Hæmodiagnosis of Appendicitis.—M. Tuffier reports the case of a patient suffering from a tumor in the right iliac fossa, which had progressively increased in size for the past eight months, was hard and indolent, and closely connected with the iliac bone. A diagnosis of osteosarcoma was made, but the writer, not being altogether satisfied, had the blood of the patient examined. Dr. Milian made the following report: "Red globules, 5,637,000 per c.mm.; white globules, 40,600, of which 75 per cent. were multinuclear, 25 per cent. uninuclear, and no eosinophiles. Too many white globules for a sarcoma, too many red globules for epithelioma; therefore it must be an abscess." This diagnosis was amply confirmed by the operation. The abscess was probably due to an attack from which the patient had suffered nine months previously, and which she attributed to poisoning, but which was in reality an attack of appendicitis with the formation of periappendicular abscess, which subsequently opened into the sheath of the psoas.—*Medical Press and Circular.*

Raynaud's Phenomena.—Jonathan Hutchinson includes under this name a large group of maladies which differ widely in their etiology. Local syncope, local asphyxia, symmetrical gangrene of the extremities, and acrosphacelus are synonymous terms, and imply the malnutrition of the parts and the local symmetrical gangrene due to interference with the circulation of the extremities. Children of five years and upward are liable to the affection through the influence of the nervous system, and old people through the influence of the heart and circulation. Treatment must depend on the case. If the nervous system is very susceptible in a reflex manner to the influence of cold, we must protect the patient from the cold. Wintering in a warm climate may be recommended. The best drug is opium, three or four drops of the tincture being given three or four times a day, in combination with tonics.—*Medical Press and Circular.*

The Pathogenesis of Spinal Curvature in Syringomyelia.—S. Nablandov relates the facts revealed at the autopsy of a patient who died of syringomyelia with spinal curvature. All the cervical and dorsal vertebræ were remarkably soft, having lost their compactness, and offering very little resistance to the saw, while all the other vertebræ were normal. The great softness of the cervical and dorsal vertebræ, especially when contrasted with the lumbar vertebræ, clearly proved that this was a case of deep nutritive changes of the osseous tissue.—*Russki Vrach.*

Thorax in All Supposed Stomach Diseases.—H. B. Garner states that all gastric processes are much influenced by the condition of the circulation. He has had many patients who, complaining of impaired gastric digestion, were discovered to have an organic heart lesion. He examines the heart in all cases of supposed stomach diseases of obscure origin, and has found cardiac lesions in about 15 per cent.—*The Practitioner and Surgeon.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, November 16, 1901.

OÖPHORECTOMY AND MAMMARY CARCINOMA.

IN the *British Medical Journal* for October 19, 1901, there are two articles, one by Beatson and another by Herman, bearing upon the influence which removal of the ovaries has upon the growth of mammary cancer, and also giving a series of clinical observations on cases in which the operation has been done and in which the after-treatment has been supplemented by the use of thyroid extract.

The reported results are important enough to warrant attention and analysis, and to this end we may epitomize them. In his present article, Beatson describes a case in a woman of forty-four, who had all the signs of carcinoma of the breast. The growth was one which would ordinarily have been considered inoperable, and chiefly for this reason a decision was reached to see what could be done by removal of the ovaries, and the internal use of thyroid extract. Oöphorectomy was done, and at the same time a portion of the tumor was removed for examination with the microscope. The patient recovered promptly; the microscope showed unmistakable carcinoma, and six months afterward the tumor of the breast had disappeared, the breast was atrophic, and the axillary involvement was reduced to practically nothing.

Herman, in the *Lancet*, June 11, 1898, reports a very similar case with like result after seven months, in a woman of forty-six, on whom the operation was performed in the presence of an extensive recurrence, and in a later contribution, mentioned above, he gives a series of eight well-advanced cases in which the same treatment was carried out. Of these eight, one was alive and well after three years, one died after eighteen months, one was dying of the disease when the paper was written, one died after two years from internal metastases, one was in good condition and apparently free from disease a year after operation, and in the three remaining cases death occurred a few months after the oöphorectomy was done. In most of the cases, thyroid extract was used as an adjuvant to the operative treatment.

The well-known tendency of all untreated cases of mammary carcinoma to end fatally makes the experiences recorded in the histories of some of these patients very remarkable, and it would be apparently unjust to deny that the removal of the ovaries had not an important influence in determining the retrograde metamorphosis which occurred in some of the cases, about the diagnosis of which there can be no reasonable doubt. There is no question that there is a very close relationship between the physiological activities of the ovaries and those of the mammary glands, but it is not yet definitely established to what extent the ovaries control the neurotrophic conditions of the breasts, or in what way this control is brought about. Beatson's idea is that the ovarian tissue, when functionating normally, exercises some sort of inhibitory influence upon the mammary cells, which, however, keep their power of proliferating, and that when changes in the ovaries diminish the control, the proliferation is resumed in an abnormal way. He also thinks that his experiences furnish strong evidence against the theory that cancer is of parasitic origin, because obviously the growth of a parasite would not be influenced by the removal of the ovaries when the site of its activities was in the breast. So far Beatson has applied this plan of treatment only to what are ordinarily called inoperable cases, and he is at present considering the advisability of using it earlier in the course of the disease.

To claim that undoubted carcinoma in the breast can have its cellular activities suspended or metamorphosed by the removal of organs which can only be connected with it through the sympathetic system—admitting that carcinoma is a pathological entity, and only shows differences according to the kind of epithelium which is the seat of its growth—is to advance a theory which, though drawing some support from the experiences of Beatson and Herman, is not in accordance with generally accepted views on cancer, and does not explain the great number of cases of that disease which do not have any connection with ovarian activity on account of sex or location.

We do not, however, understand that these English observers are advancing a theory to explain the whole pathology of carcinoma, but are merely reporting interesting phenomena, the exact explanation of which is not at present clear. The ovary is the center of sexual activity in the woman, and variations in any of its physiological activities have a profound influence upon the other elements in the sexual microcosm, whether these are in a normal condition or not. The influence of normal ovarian activity upon the growth and physiology of the breasts is too well known to need comment, but it may be well to emphasize the fact that ovarian influence upon neoplasms in the breast is also often well marked. Not that any causative relationship can be proved between mammary neoplasms and the ovarian influence, but that evidences of increased vascularity and more rapid growth are evident in tumors at different times, notably the menstrual epochs, is well known. It is quite possible that this increase in vascularity is accompanied by a nervous influence which is not evident to the senses of the observer.

It is not easy to explain the disappearance of the growth in Beatson's case mentioned above by supposing a rapid atrophy, because as far as we know rapid atrophy has never been observed in a case of carcinoma, and, furthermore, the retrogression was more like the subsidence of an inflammatory process than the occurrence of atrophy. That there was some so far not understood nervous influence at work which in some way controlled and altered the metabolism of the carcinomatous cells is pretty certain, but that this influence cannot always be depended upon is also certain, and that it is not an influence which is effective against carcinoma *per se*, but only

against a certain type or class of cellular abnormality in the breast, seems to be the case. It would be a very extraordinary circumstance if it were shown that carcinoma in other parts of the female organism were in any way influenced by the removal of the ovaries, and we do not believe that there is any evidence that this is the case. That only growths in the breast are thus influenced is probably not due to any specific anticarcinomatous effect of oophorectomy, but only to the general influence which the operation has on the whole feminine organism. The epithelium of the mammary glands happens to be that in the whole body, which is most sensitive to ovarian influences.

Observers so far have noted that the removal of the ovaries has no favorable influence upon secondary deposits in the liver or lungs, and we do not believe that women whose ovaries have been removed are afterward exempt from the development of carcinoma. The observations so far seem to show that certain forms of carcinoma are dependent for a part of their activity upon the sympathetic relation which exists between the ovaries and other parts of the body; and this, for us, tends to support the theory of the local epithelial origin of carcinoma, and to militate against the idea that the disease is parasitic.

The neurotic element in the etiology of cancer has often been discussed, but so far we have been unable to say anything very positive

In those cases in which thyroid extract has been given, its administration has been thought desirable on account of its supposed effect upon the general metabolism of the body, and not for any specific action.

THE TUBERCULIN TEST OF PURE-BRED CATTLE.

Mr. D. E. Salmon, D.V.M., Chief of the Bureau of Animal Industry of the U. S. Department of Agriculture, has recently issued a pamphlet in which he demonstrates the necessity of guarding against the importation of disease by means of imported cattle, and upholds the present regulations to prevent such occurrences as proper and consistent. The chief danger to cattle arises from the prevalence of tuberculosis, which disease affects herds more widely and more disastrously than any other.

Even if the point urged by Professor Koch at the British Congress on Tuberculosis be granted, and it is allowed that the spread of tuberculosis by milk and meat is to be feared but to a slight extent, the fact must still be borne in mind that tuberculosis, in itself, is a decimating factor among cattle of immense importance.

Mr. Salmon shows that the United States has a very large export trade in cattle, and one that is continually increasing. He further points out that rigid restrictions are in force in many countries of the world to prevent tuberculous beasts from gaining an entrance into these territories; consequently, if we wish our cattle to enter these markets, they must not only be free from tuberculosis when they leave the farm, but also when they arrive in the foreign country. To effect this object, every effort must be put forth to keep out tuberculous cattle from this country, for a few thus diseased will quickly spread contagion far and wide.

The argument is therefore advanced that the tuberculin test, as now adopted, must be strictly enforced to guard against such a result. The contention is likewise made that the pure-bred breeds, mainly imported from Great Britain, are the chief menace in this respect, and that, if the tuberculin test were not stoutly adhered to, the blue-blooded immigrants from the United Kingdom would disseminate the germs of tuberculosis among cattle from one end of the country to the other.

Evidence in support of these conclusions is afforded by the reports of two Royal Commissions appointed in Great Britain to inquire into the matter, as well as by various reports bearing upon the tuberculin test of cattle, supplied from many sources in the same country during the past few years.

Mr. Salmon makes out a strong case against the British pure-bred cattle as vehicles of tubercular infection, and urges that no discriminating favor whatever should be exhibited toward them on account of their aristocratic lineage; but, rather for the very cause that they have been proved to be peculiarly liable to tubercular disease, that the tuberculin test should be used on them in every instance.

This sounds like common sense, and, proceeding from one of Mr. Salmon's wide and varied experience, should commend itself as such, not only to the farmers, but also to the inhabitants of the United States in general. No person, whether he believes that bovine tuberculosis is communicable to man or otherwise, but would prefer to eat the meat or drink the milk procured from an animal free from disease. It therefore appears entirely reasonable, and to the best interests of the population of the United States, that the regulations of the Department of Agriculture now in force should be continued.

THE DIAGNOSTIC VALUE OF THE BLOOD-SERUM REACTION IN CHILDREN.

Typhoid fever is apparently less common, and in general it pursues a milder course, and the possibility of error in diagnosis is therefore greater in children than in adults. The value of the agglutinating and sedimenting reaction of Gruber and Widal in the diagnosis of typhoid fever has been abundantly demonstrated, and the procedure is now one of the usual means of recognition and differentiation. It has been contended, however, that the test is not so trustworthy in the case of children as in that of adults; but with this view Dr. J. H. Thursfield (*British Medical Journal*, September 7, 1901, p. 596), on the basis of a considerable experience, does not agree. Of 100 cases presenting different disorders in children, a positive response was obtained in forty-two. As so much depends upon the technic employed, that, followed in these observations, may be described. A small quantity of blood in a sterile glass pipette is diluted with an equal quantity of sterile broth, and the pipette is placed in a centrifugal machine for the separation of the blood corpuscles. Then to one platinum-loopful of the diluted serum on a cover-slip are added fifteen loopfuls of a broth culture of typhoid bacilli, not more, and usually considerably less, than twenty-four hours old, prepared from a stock culture renewed from time to time from a trustworthy source. The cover-slip is secured to the slide by means of paraffin, in order to prevent evaporation, and is examined at intervals to the end of an hour. Should clumping not have occurred, the reaction is considered negative. To guard against possible

error, a control test may be made with the blood of a patient known to be suffering from typhoid fever, and which has previously yielded a positive reaction. A positive result was not obtained in any case in which the condition present was not at least more like typhoid fever than any other disease, while in no case that was clinically an example of typhoid fever did the reaction fail to appear. From these observations the conclusion is drawn that in disease in children a positive serum reaction is trustworthy evidence of the presence of typhoid fever; that a negative reaction later than the tenth day of an illness is strong, but not absolutely convincing, evidence of the absence of typhoid fever; that repeated negative reactions are trustworthy evidence that the disease is not typhoid fever at all. The test is, further, believed to be of greater value in the case of children than in that of adults, inasmuch as it is generally possible to exclude the occurrence of a previous attack in the former, while this cannot be done in the latter, and it may be a source of confusion, if not of error. In addition, it is thought that the reaction occurs earlier in children than in adults.

News of the Week.

Naval Department, Bureau of Medicine and Surgery, Washington, D. C.—Changes in the Medical Corps of the Navy, week ending November 9, 1901: November 1—Surgeon F. Anderson, detached from the Naval Dispensary, Washington, D. C., November 7, and ordered to the *Alabama*, November 9, as relief of Surgeon E. H. Green. Surgeon E. H. Green, detached from the *Alabama* November 9, and ordered to duty as a member of the medical examining board, Washington Navy Yard, November 15, as relief of Surgeon A. C. H. Russell. November 2—Medical Director J. G. Ayers, retired from active service November 3, 1901, by operation of law, under the provisions of section 1444, Revised Statutes, upon which date he will have reached the age of sixty-two years; with rank and three-fourths the sea pay of the next higher grade, under the provisions of section 11, Navy personnel law. November 6—Assistant Surgeon R. M. Young, detached from the *Columbia* and ordered to the *Constellation* for temporary duty.

Buck's County (Pa.) Medical Society.—At the annual meeting held November 6th the following officers were elected for the ensuing year. *President*, Dr. Howard A. Hellyer of Penn's Park; *Vice-Presidents*, Drs. Henry Lovett of Langhorne and Alfred Fretz of Sellersville; *Secretary and Treasurer*, Dr. E. A. F. Myers of Blooming Glen.

Philadelphia Hospitals.—An appropriation for $963,381 has been asked for by the Bureau of Charities, for the year 1902, including $365,000 for new buildings, as follows: A pavilion for tuberculous patients, $80,000; a clinical amphitheater, $100,000; obstetrical and gynecological hospital, $85,000; pavilion for nervous diseases, $50,000; pavilion for general medicine, $50,000.

Elisha Kent Kane Medal.—Dr. A. Donaldson Smith of Philadelphia has been awarded the Elisha Kent Kane Medal by the Geographical Society of Philadelphia in recognition of his extensive explorations in the previously unknown region of the Upper Nile in the year 1900. Dr. Kane, the Arctic Explorer, left a fund to be distributed in medals for distinguished services in adding to the known geography of the world. Dr. Smith is the first recipient of the honor.

The Second International Congress of the Medical Press, which was to have been held in Brussels in 1901, has been postponed for a year because of the impossibility of arriving at a satisfactory decision concerning the constitution and by-laws of the proposed international association of the medical press.

A Fasting Woman, named Christiansen, has just completed a thirty-day fast in London. She lost twenty-six and one-half pounds in weight, but declared to the reporters that she was in good health and spirits. She threatens to inflict herself upon New York soon.

The End of the Proposed Skene Hospital.—Supreme Court Justice Maddox in Brooklyn has granted an order dissolving the Skene Hospital for Self-Supporting Women. The petition says that $300,000 was necessary to carry out the project and that only $23,000 was subscribed, of which only $3,261 was paid. The hospital was to be erected as a memorial to the late Dr. A. J. C. Skene. The order directs the distribution of the $3,261 among the contributors.

The South African Reconcentrados.—According to the official reports on the condition of the Boers in the concentration camps in South Africa, the mortality, chiefly among the children, is increasing at such a frightful rate as to threaten the prisoners with extinction. In June there was a total of 85,410 Boer reconcentrados, and the mortality was at the annual rate of 109 per thousand; in July there were 93,740 inmates of the camps and the mortality rose to 180 per thousand; in August, with 105,340 prisoners, the mortality rate was 214; in September it was at the annual rate of 264 per thousand in a reconcentrado population of 109,418. The *Daily News* of London, in commenting upon these figures, says: "The truth is that the death rate in the camps is incomparably worse than anything Africa or Asia can show. There is nothing to match it, even in the mortality figures of the Indian famine, where cholera and other epidemics have to be contended with."

A Pharmaceutical Association.—It is said that a number of the retail druggists in New York City are going to manufacture their own elixirs, emulsions, fluid extracts, etc., which heretofore they have purchased from manufacturers who make a specialty of such preparations. A coöperative organization, known as the Pharmacists' Manufacturing Company, has been formed and incorporated for this purpose.

A New Smallpox Hospital in Newark.—Two portable wards and an administration building have been contracted for by the Newark, N. J., Board of Health, and the work of erecting them was begun this week. It is expected that they will be ready for occupancy in a fortnight. The hospital is intended for smallpox patients, the number of which is daily increasing and already exceeds the capacity of the present small building used as an isolation hospital.

Dr. Hamilton Williams, the Coroner's physician who was recently removed by Coroner Zucca on charges of incompetency, neglect of duty, and unfitness to hold office, has been reinstated by the Supreme Court which holds that the power of trial and removal rests solely in the full board of coroners, and not in any individual member. The animus of the charges is said to have been political, and as Coroner Zucca was relegated to private life

at the recent election, the charges will perhaps not be pressed.

The State Hospital for Consumptives. Mr Littauer has offered to present a tract of 160 acres of land at Forestport, Oneida County, for the location of the New York State Hospital for Incipient Tuberculosis. The land, which is said to be most suitable for sanatorium purposes, has been inspected by the State commission, but the report has not yet been published.

The St. Louis Academy of Medicine.—At the recently held annual meeting of this society, the following officers were elected: *President*, Dr. A. C. Bernays; *Vice-President*, Dr. J. W. Williamson; *Secretary*, Dr. Alfred Roulet; *Treasurer*, Dr. George Howard Thompson.

The Idaho State Medical Society.—At the annual meeting of this society, held at Pocatello, October 3 and 4, the following officers were elected: *President*, Dr. H. A. Castle of Pocatello; *Secretary*, Dr. E. E. Maxey of Caldwell; *Treasurer*, Dr. J. W. Givens of Blackfort. The next annual meeting will be held at Moscow, October 9 and 10, 1902.

An International Sanitary Congress will be held in Paris during the week of February 15-21, 1902. Among the subjects to be discussed will be the rôle of mosquitos in the spread of yellow fever, malaria, filariasis, quarantine, and the value of municipal sanitation in the prevention of epidemics.

Tunnel Ventilation.—The following remarks of *The Lancet* are of special interest to New Yorkers at the present time, when it is possible to gather from the experience of others the desirable ounce of prevention. Our contemporary says that the measures adopted on the Central London Railway for the ventilation of the "tube" are, in face of the enormous number of people daily traveling on the line, inadequate. "We pointed out some time ago that it is well known that the air of the 'tube' has not grown pleasanter as the popularity of the system has increased. Even on passing the booking offices of the stations or the lift exits, an unpleasant sickly whiff is experienced. Our remarks are now fully borne out by the results of a series of interesting experiments made by Mr. A. Wynter Blyth, the medical officer of health of St. Marylebone, and his son. It is found that the carbonic-acid gas at some stations was no less than 10.3 parts per 10,000, while between the stations—that is to say, in the tunnel—it reached 11.0. Now, since the average amount of carbonic-acid gas in the outer air seldom exceeds 4 parts per 10,000, and that, whenever the amount of carbonic-acid gas in the air of a room exceeds this amount by 2 parts per 10,000, it is not fresh, and has a stuffy smell, 6 parts per 10,000 has been fixed as the limit of impurity. The 'tube' air contains nearly twice this amount. We remarked long ago that it is nonsense to say that the mere passage of the trains through a tight-fitting tunnel is sufficient to insure satisfactory ventilation. Mr. Wynter Blyth's experiments clearly show that, where the ventilation depends entirely on the passage of the trains, although there is so much movement of air, and so much sucking in from above and blowing out from below, a good portion of the air must be driven backward and forward unchanged in the tube; in other words, the tunnel air is diluted, but the whole of it is never swept out. This has all along been our contention. The amount of carbonic-acid gas in the tunnels and, be it remembered, this is very largely, if not entirely, of human origin, is more than double that of the outside air. It would be interesting to know what a bacteriological examination would reveal. As time goes on, unless additional and more effective ventilation by fans is adopted, the condition of the tunnel will go from bad to worse. These observations might usefully have been extended to the air of the cars; the results would probably have shown a greater pollution still."

The Craig Colony Prize of $200 has been awarded to Professor Carlo Ceni of Pavia, Italy, for an essay, entitled "Serotherapy in Epilepsy." The essay will be published shortly.

The Combat Against Tuberculosis in Ohio.—One hundred and fifty physicians, sanitarians, and business men of Ohio have united to form a society to be called the "Ohio Society for the Prevention of Tuberculosis." The first move of the society will be along educational lines. It will distribute pamphlets giving precautions that should be exercised to prevent transmission of the disease. There will be lectures in large shops, before teachers' meetings, and other public gatherings all over the State. The society will also aid in the establishment of a hospital for the treatment of all consumptives whose cases are regarded as curable, and also the establishment of hospitals for consumptives in all the larger cities of the State.

Spread of Scarlet Fever in a School.—During the past few weeks from ten to fifteen cases of scarlet fever have occurred each week among the four hundred children attending a public school in one of the city's suburbs. The first case was in a girl who was slightly ill for a few days, but the family had no physician, and did not know what the disease was. As soon as she became convalescent, she returned to the school, and her mates amused themselves by picking off the strips of desquamating epidermis.

Medical Department of the University of California.—Beginning with the academic year 1905-06 all students desiring to enter the first year of the medical course in this university and all new students seeking advanced standing must present evidence of having completed at least two full years of preliminary training in the undergraduate department of a college or university of recognized standing. Satisfactory evidence must also be presented that during these two years the applicant has completed courses in chemistry, physics, biology, English, German, and French.

The Virchow Hospital.—It was recently voted by the municipal authorities that the new public hospital in Berlin, now in course of erection, be called the "Virchow Krankenhaus." The hospital will have accommodations for 1,700 patients.

The Fourteenth International Medical Congress.—The committee on organization of the Madrid Congress, to be held April 23-30, 1903, announces that, in response to numerous requests from Spanish and foreign specialists, the following changes have been made in the constitution of the sections: Section 11, on Otology, Rhinology, and Laryngology, will be divided into two sections, viz.: 11a, Otology, and 11b, Rhino-Laryngology. These two sections will be independent one of the other, each having its own president and secretary. The sixteenth section, on legal medicines, will be entitled the Section on Legal Medicine and Toxicology. The dues for members of the Congress will be 30 pesetas (80), and a novel condition of registration is that each member shall send to the Secretary-General of the Congress, either directly or through his

national committee, not only the fee, but also a note indicating precisely and legibly his full name and address, his titles and appointments, and his photograph. The official languages of the Congress will be Spanish, French, German, and English.

Money for Guy's Hospital.—A dispatch to the *Sun* states that Mr. J. Pierpont Morgan has promised to give £5,000 to Guy's Hospital on condition that the public will raise £100,000, which is required for the renovation and extension of the hospital.

A New Hospital in Manchester, N. H.—Under the will of Mrs. Emiline Balch of Manchester, N. H., the balance of the estate, after the payment of $25,000 in bequests to various charitable, religious, and educational institutions, is left to five trustees commissioned to establish a hospital to be known as the Balch Hospital, in Manchester. The amount available for this purpose is believed to be about half a million dollars.

Consumptives in Railway Cars.—The Travelers' Protective Association recently requested the members of the Western Passenger Association to provide separate coaches and sleeping-cars, or at least separate compartments in the sleepers, for tuberculous travelers. The protective association complained that the health and life of its many thousands of members were daily being placed in jeopardy through mingling on sleepers and coaches with consumptives. The same request is to be made of the Transcontinental Passenger Association, which meets soon. The railway men refused to take action, but passed a resolution that the problem and its solution belonged properly to the Pullman Company and not to any of the railroads over which the Pullman sleepers ran.

The Plague.—The period of incubation since the last case of plague in Glasgow expired last Saturday without any fresh cases being reported. The authorities consider that the disease has been stamped out. The crusade against rats continues, however, for it is believed that the outbreak of the plague was due to these animals. Those which were caught in the Central Station hotel, in which several persons suffering with the disease were discovered, were found to be infected. Germany has nevertheless established a quarantine against Glasgow, and an order has been issued forbidding the importation into or transport through Germany of body linen, old clothes, rags, or used bed linen from that city. An exception is made for luggage and a change of clothing, but these are liable to be disinfected. It is reported from Hull, England, that a death, thought to be from plague, has occurred on board a steamship there.

Obituary Notes.—Dr. CHARLES MAGILL SMITH died at Franklin, La., on November 7, at the age of seventy-six years. He was born in Winchester, Va., was graduated from the Medical Department of the University of Pennsylvania in 1847, and began the practice of his profession in Louisiana the following year. He was for many years President of the Louisiana State Board of Health, and had been Coroner of St. Mary's Parish for twenty-two years.

Dr. CHARLES N. SPALTER was accidentally shot and killed on November 7, while duck hunting with another physician on the Sound near New Rochelle, N. Y. Dr. Spalter was born in Keene, N. H., about twenty-seven years ago, and had just served a term of service on the house staff of the Woman's Hospital.

Dr. HARVEY P. TOLMAN died at his home in East Onondaga, N. Y., on November 11. He was born in Pompey, N. Y., on July 12, 1823, and was graduated from the College of Physicians and Surgeons of this city in 1848.

OUR LONDON LETTER.

(From Our Special Correspondent.)

SMALLPOX — VACCINATION STORIES — SOCIETIES — ACUTE DILATATION OF THE STOMACH — "RESPONSIBILITY OF THE ORGANISM" — GLAUCOMA — LATERAL CURVATURE OF SPINE — ENTRIES AT THE SCHOOLS — OBITUARY NOTES.

LONDON, October 25, 1901.

SMALLPOX continues to prevail with unpleasant persistency and a tendency to spread to other districts is noticeable. Yesterday eleven fresh cases were reported, bringing the number under treatment to 170. The type of the epidemic seems grave, and the mortality rather high. Eleven deaths from the disease were registered last week. This is the highest record for any week since the outbreak.

The middle and upper classes are being revaccinated on so extensive a scale that it is rare to meet any of them who have not taken the precaution. Large numbers of the working class are following the example, and the free vaccination stations are consequently crowded. The medical officers of health are doing all they can to promote revaccination. One instance of their activity comes to my notice in a circular from a public school saying that the officer in question had recommended parents to be informed that he considered it very desirable. The school authorities indorsed the hope that the precaution would be adopted. How different this attitude to the obstruction of the London School Board which I have mentioned to you before. Yesterday this board was again made ridiculous by one or two obstructives venting their indignation on a vaccination officer who, they declared, had bribed some of the children of a board school with boxes of chocolate to submit to the operation, which he actually told them did not hurt, and would prevent them from catching smallpox. Think of the dignity of the board entrusted with the supervision of London schools, and you will no doubt wonder at the temerity of any one giving a scholar a chocolate without permission first applied for! The board was actually thus prevented from circularizing the parents, and advising them to forbid their children to accept the chocolates. You see, it was absolutely necessary to devote most of the time of yesterday's meeting to the vindication of the dignity of the board. Another curious story is being made the most of by some of the newspapers. It seems that a circular was sent to the friends of the lunatics in one of the asylums asking if they had any objections to the patients being vaccinated. The list could not have been properly checked, for one of the circulars was to a relative who, a day or two previously, had been summoned to take farewell of a dying patient. Deathbed vaccination is too taking a paragraph for certain newspapers to omit it.

Mr. G. B. Shaw, whose name you may know as to theatrical matters, is not content to confine his criticisms to subjects he has deeply studied. He has been writing to the *Times* and other papers, and proving as a great statistician so far as to rebuke doctors for their ignorance of the statistics of vaccination. He tells us there is no science of medicine; but there is, of course, of statistics, since he has shed his light on figures. Better housing for the poor is one of his hobbies, and a very good one, too; but to hold it up as a protection against smallpox in place of vaccination is dangerous. Mr. Shaw assumes knowledge of so many subjects that the public is amused at his pretensions, and does not take him seriously; so his influence against vaccination is not great, especially as he protests that he is not an anti.

The Royal Medico-Chirurgical Society began the session with a paper on "Acute Dilatation of the Stomach," by Dr. Campbell Thomson. He described four cases of his own and six others, making ten that have been recorded. The first to describe it was Dr. Hilton Fagge, who recorded four of the ten. A summary of the symptoms and post-mortem appearances was given, but it would seem that quite half the cases presented other lesions sufficient to account for death. Dr. Thomson was inclined to regard the dilatation as due to some disturbance of the nervous supply of the stomach, paralyzing its walls and often setting up, as well, increased secretion.

Dr. T. R. Bradshaw thought the cases were obviously due to pyloric obstruction. If the walls were paralyzed, the stomach could not empty itself, and yet vomiting was prominent. In all the cases the intestines below the pylorus were collapsed, pointing to its obstruction.

Dr. Herringham pointed out that the stomach was probably distended by the gas described as present, and that might suffice to overcome the pressure of the abdominal walls.

Dr. A. Voelcker thought the presence of bile in the vomit, which had been observed in two of the cases, was against the view of pyloric obstruction.

The President (Dr. Pavy) did not believe that active

dilation could occur. He regarded the stomach as he did any other hollow viscus. It dilated when the pylorus was obstructed, as the bladder did when its contents could not be evacuated. Atony or paralysis of the walls combined with expansion by fluid or gas would distend any hollow organ. He referred to experiments on dogs in which both vagi had been divided. The lower end of the œsophagus thus paralyzed was found distended with any food taken shortly before death.

Dr. Thomson, in his reply, referred to the heart as a hollow viscus which dilated primarily without a previous necessary obstruction of the aorta.

Dr. Allchin, on taking the chair as the new President of the Medical Society of London, gave an address on what he termed the "Responsibility of the Organism" in disease, in which he dealt with the part taken by the individual as distinct from the environment, in the manifestation of disease. The capacity of the organism to react to external agencies, however simple or however complicated these may be, certainly deserves attention, especially at this time, when so great an impetus has been given to the study of the environment. It is quite possible that too little attention may be given to the individual and the part he takes in the origination of disease, or, what is more important, the part he should be made to play in its prevention and treatment. In illustration of this, Dr Allchin observed that the bodily states regarded as heritable are fewer than formerly supposed, and their transmissibility less potent than was thought; in other words, it was less the disease itself than a tendency toward it which required the conjunction of external conditions to develop it, though the predisposition was so strong as to assert itself in spite of the best environment. Prominent among conditions tending to recur in successive generations were longevity and the reverse, obesity and leanness, and a group in which nutritive disturbances were concerned, *e. g.* gout and diabetes. The undoubted influence of age and sex was further instanced. Dr. Allchin suggested that the society might undertake a collective investigation into undetermined questions in clinical medicine. He thought the society eminently fitted for such work, and reminded it that nearly a hundred years ago the Fellows had done something of the kind as to influenza.

The President of the Ophthalmological Society devoted his address to "Primary Chronic Glaucoma," for which he said the profession remained unanimous that iridectomy was the only cure. Following up the work of v. Graefe, others, whose researches he mentioned, had done much to elucidate the pathology of the disease and to establish the treatment. He was in favor of early operations.

Mr. Nettleship proposed a vote of thanks, and indorsed the president's views. Mr. Silcock seconded the motion, which was unanimously carried.

At the Orthopedic Society, Mr Reeves showed five interesting cases, and Mr. Muirhead Little read a paper on the "Treatment of Lateral Curvature of the Spine," which was discussed by Messrs. Reeves, Keetley, and others.

There is a decrease in the entries of students, both in the London and Provincial schools. This is not pleasant for some of the teachers, but satisfactory to many hard-worked practitioners.

Two nonogenarians passed away on the 17th inst. One was Robert Hepburn, a prince in the dental profession, successful in London at an early age, a man of fine physique, with rich mental endowments. He was to the fore in every effort to raise the status of dentistry and promote its scientific progress. He took a leading part in founding the Dental Hospital, and has lived to see it become the Royal Dental Hospital of London. He was also to the front in establishing the Odontological Society of which he has served in the presidency. A very remarkable man also socially, and a generous philanthropist. He died in the house so long associated with his name and work in Portland Place, aged ninety-two years.

The other venerable gentleman who died on the same day was Charles Holding, F.R.C.S., Eng. He took the M.R.C.S. and L.S.A. as long ago as 1830, having studied in the old united school of Guy's and St. Thomas's, and also at Edinburgh. He was made a Fellow of the College of Surgeons in 1855 and a licentiate of the Edinburgh College of Physicians in 1880. He reached the age of ninety-three years and nine months.

The death of Dr James Foulis, M.D., F.R.C.P., Edin., at the comparatively early age of fifty-five, removes a notable and successful practitioner from the Scottish capital. He graduated in 1872, and was elected a Fellow of the Edinburgh College of Physicians in 1888. He was too busy to write much, but in the early part of his career he contributed to the Royal Society of Edinburgh an important research on the "Development of the Ova and the Structure of the Ovary in Man and Other Mammalia," a subject which he afterward followed with interest, especially in relation to ovarian disease.

Dr. E. H. Dickinson of Liverpool died on the 12th inst. For more than thirty years he was physician to the Northern Hospital, an appointment which he resigned last spring on account of failing health. He took his M.D., Edin., in 1876, and was elected F.R.C.P. in 1880. He graduated in Arts at Oxford. He wrote a treatise on the "Medicine of the Ancients," and contributed practical papers to the societies.

Other recent deaths are:

Surgeon-General W. A. Thomson, M.B., Hon. Phys. to the King, died on the 6th inst., aged seventy-one years. He entered the army in 1851, and retired in 1892.

Dr Aplin, on the 21st Superintendent of Notts County Asylum, aged forty-seven years.

Dr Bentham, formerly superintendent of London House Asylum, and since medical adviser of various charitable institutions in which he took great interest. He died on the 15th, aged eighty-one years.

The Rev. J. Dalzell, M.B., M.A., B.D., of the Gordon Memorial Mission in Natal, died on September 21, aged sixty years. He served as surgeon in the Zulu War, for which he had the medal.

Henry Duncalfe, M.R.C.S., who qualified in 1851, and long held a superior position in the Midlands, both as a medical man and a promotor of public works. He retired in 1874. He died suddenly on the 20th inst., aged seventy-three years.

James Livingstone, M.D., J.P. of Wishaw, on the 4th inst., aged sixty-seven years.

OUR PARIS LETTER.

(From our Special Correspondent.)

CHAUFFARD'S OPINION OF HAYCRAFT'S TEST—THE BUBONIC PLAGUE ON BOARD THE "SENEGAL"—THE PLAGUE AT NAPLES—CALCAREOUS STRICTURE OF THE URETHRA—SUPPOSED CASE OF DEATH FROM MEDULLAR COCAINIZATION—DR. CROSTI'S REMARKS ON BASSINI'S OPERATION—CONGRESS OF GYNECOLOGY AT NANTES—FOURTEENTH CONGRESS OF MEDICINE—DREYFUS-BRISSAC ON TREATMENT OF PNEUMONIA.

PARIS, October 18, 1901.

DR. CHAUFFARD, who is the best-known liver specialist in France since Hanot's death, has been investigating with Dr. F. X. Gouraud Haycraft's method of recognizing in urine the presence of minute quantities of biliary products. According to Chauffard, this test should be carried out on perfectly fresh urine, or urine that has been preserved from all fermentation by the use of a small amount of cyanide of mercury—for instance, five to six centimeters of a 2-per-cent. solution. The urine should be poured into a glass, and a small amount of powdered sulphur deposited very carefully on the surface of the liquid. If there is bile in the urine, a certain amount of sulphur falls to the bottom of the glass. The time limit should be, according to Chauffard, about five minutes. Haycraft's test reveals the presence of biliary salts or bilirubine, even when the solution is 1 in 50,000. Pettenkofer's test gives no result over 1 in 1,000. Clinical experiments were carried out on fifty samples of urine, and there was a positive reaction twenty times. This was found to be correct by the use of the spectroscope and of Salkowski's test, which is even more delicate. The *Revue Générale des Sciences* had organized a scientific excursion on board the steamer *Sénégal* which left Marseilles on the 14th of September for Asia Minor and Palestine. Two or three days after the departure, two cases of bubonic plague were discovered by the medical officer, and the steamer was obliged to put back to Frioul, the lazaretto of Marseilles. There were nineteen physicians on board, and among them Drs. Terrier Bucquoy, Chauffard, Richardière, Castex. All the passengers and crew, with the exception of thirteen, were inoculated. One of the two patients has already died. On the night of the 23d of September, the prefect of Naples notified the Minister of Interior at Rome that some suspicious cases of what seemed bubonic plague had broken out among the workmen employed at the Punto Franco. The necessary precautions were immediately taken.

It seems probable that at one of the next meetings of the Academy of Medicine there will be an "interpellation," according to parliamentary language, on the means employed at Frioul to insure complete disinfection.

There would seem to be a rumor current that, for instance, of the two openings in the "étuves" only one is used; that in one case of bubonic plague on board a steamer coming from Suez the passengers were landed eight days after their arrival, given a bath, and subjected to relative disinfection, and disembarked the next day at Marseilles. It would also seem that in case of hemor-

hage the physician in charge was obliged to borrow a solution of ergot from one of the physicians on board the ships stationed in the harbor. At a recent meeting of the Society of Surgery, Dr. Bazy spoke of a peculiar case which had been treated by Dr. Dupraz of Geneva. The patient, a mason, had injected limewater into his urethra as a means of curing gonorrhœa. He had continued this treatment for several months, and when Dr. Dupraz examined him, he found a stricture extending nearly the entire length of the urethra, and admitting only a No. [illegible] bougie. This stricture was the result of a chalky deposit. Curettage was found inefficient, and Dr. Dupraz used injections of a 1 per 1,000 solution of hydrochloric acid. This deposit had disappeared after twelve injections.

A few weeks ago, several political journals spoke of a case of death from medullar cocainization, which had taken place at the Beaujon Hospital. A woman, suffering from a wound of the foot, had been anæsthetized by Tuffier's method, and had died a few hours afterward. The facts presented in this manner seemed to be most serious. It would seem to be, however, as usual, what they call in French a "canard," showing once more the tendencies of the press to incriminate physicians when they can. The surgeon who had operated this patient, Dr. Lyot, wrote to the *Presse Médicale* and indicated in what manner death had taken place.

The patient showed symptoms of septicæmia, the third after the accident, the temperature being at 40°; the tongue is dry, there are diarrhœa and incontinence of urine. Before the operation, an injection of one and a half cubic centimeters of cocaine solution was made, and the astragalus was removed. The temperature remained at 40° after the operation, and death took place the next day. Dr. Lyot said that there were no symptoms of poisoning by cocaine, and that the autopsy revealed no lesion of the spinal cord.

Dr. Crosti, surgeon of the Hospitale Maggiore at Milan, has been performing some operations in Professor Reclus' service at the Laennec Hospital.

According to Dr. Crosti, one of the important points in Bassini's operation is overlooked by a certain number of operators, not only in Paris, but elsewhere. The latter is that by which the posterior wall of the new canal is formed by the union of the fibers of the rectus, transversalis, and minor obliquus to the deep part of Poupart's ligament. It is necessary to separate these fibers from the adponeurosis of the major obliquus and the subserous adipose tissue, so that there should be no tendency to pull on these tissues to bring them together. Dr. Crosti believes in using silk for these deep sutures, and in places, such as Perouse, Sienna, or Rome, silver wire is used.

At the Congress of Gynecology, Obstetrics, and Pediatrics, held recently at Nantes, a question which was very much discussed, and which was the subject of a long report by Drs. Olivier and Schmitt of Nantes, was "the defence of children." Dr. Olivier said it was necessary that a pregnant woman should have complete rest six weeks before and six weeks after delivery. An indemnity equal to two-thirds of the salary earned by the woman should be given her during that period. There is already a law in France, called the Roussel law, which provides for the medical supervision of all infants who are not cared for by their parents. The orator recommended that all infants during the first year should be examined and reported on medically every month during the winter, and every fifteen days during the summer. Professor Pinard made several remarks on the desirability of teaching children and young people some of the reasons why they should take care of their health for ultimate reasons. A rest of at least three months should be allowed women before parturition. Dr. Pinard said he did not believe in "crèches," as he thought it unwise to take the child away from its mother. Dr. Pizzi deprecated the tendency shown in schools to force the students to learn too much, so as to pass an examination at a certain stated time.

The following resolution was passed by the Congress. "All pregnant women should be placed in the best hygienic conditions during the last three months of their pregnancies, and the first month following delivery, and the public authorities are called upon to find the best methods of insuring the realization of this measure."

The preparatory work of the Fourteenth Congress of Medicine has already begun. The President will be Professor Julian Calleja y Sanchez. The General Secretary, Dr. Angel Fernandez Caro y Nouvilas, and the Treasurer, Dr. José Gomez y Ama. This congress will take place in Madrid in 1903, from the 23d to the 30th of April.

Dr. Dreyfus-Brissac, a well-known physician of the hospitals, treats pneumonia by ipecac when the stomach and heart do not show indications of advanced lesions. The patient is given every hour a soupspoonful of powdered ipecac 1 gram: julep, 120 grams. Care should be taken to avoid both vomiting and diarrhœa. When this preparation has been absorbed, [illegible] alcohol [illegible] spartein and caffein, if necessary. This treatment would seem to relieve the dyspnœa, increase the expectoration, and diminish the temperature.

THE DISADVANTAGES OF SULPHATE OF COPPER IN DISEASES OF THE EYE

To the Editor of the Medical Record.

Sir: Allow me a few words in rejoinder to the letter of Dr. Claiborne, Medical Record, October 2[illegible].

In my opinion it is my duty, as well as my privilege, to criticise a method of treatment which my experience has taught me is a bad one, or the use of a remedy which I believe to be pernicious in its effects. Hence my criticism of Dr. Claiborne's paper. I hasten, however, to exculpate Dr. Claiborne in the matter of the treatment of the case of mixed infection cited by me. I regret very much that such an inference that I had referred to Dr. Claiborne might seem possible. I do not hold that atropine is indicated all the time in every case of trachoma. I say that it should be used in every case of conjunctival or corneal affection in which there is photophobia, ciliary spasm, or even excessive lachrymation, and these conditions are always present in trachoma with ulceration of the cornea. I cannot commend Dr. Claiborne's guess when he inclines to the opinion that the iritis in the case of mixed infection resulted from the perforation of the cornea. As a matter of fact, the iritis had existed for a long time before; and immediately began to improve when the anterior chamber was evacuated by the ulcer. Dr. Claiborne will pardon me when I remind him that such a result would be the thing to expect. The doctor's presumption is again at fault when he presumes that it was I who did the iridectomy in that case. The operation was well done by a better surgeon, and the resulting V. 5/200 was not in any way attributable to the operation. I, however, had the supervision of the after-treatment. I am very glad to hear that the type of trachoma in Berlin has been modified by Dr. Hirschberg's use of silver in its treatment there. I can well conceive such a thing possible. It is furthermore a most regrettable thing that New York does not possess more followers of that surgeon. I am familiar with the type of trachoma described by Dr. Claiborne, among the Hibernians and the Poles of New York, and for six years I touched them and saw them touched, *secundem artem*, with sulphate of copper. I was among them long enough to see some of them grow from youth to completed adolescence with their trachoma unchanged for the better: I make no manner of doubt but that Dr. Claiborne is treating some of those people yet, and that they come smiling up to the copper, a bit grizzled, alack! by these twenty-five years, but "used to it," . . . and finally inconvenienced almost to no extent;" but it doesn't speak well for copper. I am pleased that Dr. Claiborne should at least agree with Dr. Knapp and myself as to the culpability of those who fail to recognize and properly treat an iritis. However, the sentence following: "But Dr. Knapp has never suggested to treat a patient for iritis when there is none," would seem to be most irrelevant and not in the pleadings. I said nothing in my paper of Dr. Knapp's treatment or failure to treat an iritis. I am rather pleased at Dr. Claiborne's astonishment at the cases detailed by me, which must have been profound, or he would not have taken the liberty of misrepresenting what I had said. I did not say that the patient R. had been treated by "six or eight eminent surgeons," but that he had been treated by "six or eight men more or less eminent." (I think that the gentleman was not treated in New York, or I should not have called attention to the correction. Further, I did not say that I had "cured this patient completely" in three months or in any other time, but that "under the treatment outlined above, he was immediately relieved and able in three weeks to return to his work, using the bichloride at home; in three months the eyes were practically well, and have remained so now twelve years."

The specific character of the disease did not again assert itself, and gradually the infiltration of the conjunctiva subsided. Dr. Claiborne will never see a "cure" of a trachoma effected in any other way, whatever the treatment used. I would not accuse Dr. Claiborne of "scientific untruth," but, in the interests of the younger men of the profession, I also would uncover a faulty method of treatment and indicate its perniciousness. Further, now, that Dr. Claiborne has rejoiced, I would add that I said essentially the same things before the Ophthalmological Section of the American Medical Association in 18[illegible] that I have mentioned in my criticism of Dr. Claiborne's paper. I regret that the opportunity may not be mine of demonstrating to Dr. Claiborne, at first hand, the efficacy of the method of treating trachoma which has made such a shocking impression upon his mind; but if the doctor is

inclined to play fair and really in earnest, I now ask him to give the plan an honest trial and report his results as honestly. If he declines this challenge, then I name him a slave to the specific habit, a victim of cupreous hemianopsia, and addicted with psychic pseudo-scientific myopia, and that he keep his peace.

CORNELIUS WILLIAM, M.D.
[illegible] Fifth Street St. Paul.

TO GUARD AGAINST THE BITE OF THE MOSQUITO.

To the Editor of the Medical Record.

Mobile, Ala., October 29, 1901.

SIR: Referring to the transmissibility of malarial and yellow-fever infections by means of mosquitos, and the possibility of keeping these pests from biting by the use of the essential oils, I notice (*American Medicine*, October 26) E. A. H. recommends oil of cassia instead of oil of pennyroyal, as recommended by V. H. McKnight (MEDICAL RECORD from *Philadelphia Medical Journal*).

Dr. Walter Reed (MEDICAL RECORD, October 26, 1901) recommends the use of camphor, menthol, or pennyroyal to rub the exposed surfaces when visiting yellow-fever cases.

The interest taken in this subject is natural since, if the mosquito does not bite one, *she* cannot convey infection. A prevention which I have used for some years when out fishing or hunting in swamps where mosquitos were prevalent, and in the evenings when sitting out-of-doors, and which I have found to be most excellent and efficient, is the oil of citronellæ (oil of verbena, Indian melissa oil). It has a very pleasant odor, and is not expensive. The oil should be rubbed into the exposed parts, and repeated occasionally, or the following is quite as efficient:

℞ Oil citronellæ ..... ʒj
Alcohol ..... ʒj.

S. Apply freely to face, neck, hands, and ankles, to prevent mosquitos from biting.

Color this with something to make it slightly green, and you have the preparation known as "Skat Skecter," "No Mosquit," etc., sold in the shops, and rather extensively used in some of our Southern cities.

W. P. McINTOSH, M.D.,
(Surgeon M. H. S.).

ANTISEPTIC SURGERY IN THE PHILIPPINES.

To the Editor of the Medical Record.

Oras, Samar, P. I., September 24, 1901.

SIR: A short time ago I was landed with one company of infantry on the eastern coast of the Island of Samar, which is about as desolate a place as one could well find. The battalion which was sent to this island was divided into four parts, and each company sent to a different place, and widely separated. The medical property was likewise divided, each one being cut short, and my surgical equipment consisted of one small pocket case. The second day after landing, a native spy was shot by one of the soldiers on outpost, the bullet entering the posterior part of the thigh, near the junction of the middle and lower thirds, striking the femur and producing the most extensive comminuted fracture and laceration of soft parts I have ever seen. The anterior part of the thigh was laid open for a distance of six inches, and large pieces of shattered bone were plainly visible. The popliteal artery had escaped, but there was considerable hemorrhage from the smaller vessels. Amputation was the only thing like fair treatment for the unfortunate hombre, but what to do it with, was the question. The company cook said he had a butcher saw, but it was very rusty, so I told him to put it on to boil, and we would try it. I then got out my other instruments, consisting of two hemostatic forceps, a small scalpel, and two needles. The native was then placed on an old table, in the broiling hot sun, for we had no houses or shade, and the parts were washed up a bit. After getting the patient anæsthetized, I intrusted that part of the job to a big fellow, one of my assistants, and proceeded with the operation. While I was slowly cutting my way down to the bone with the little scalpel, I was interrupted by the anæsthetizer saying, "Sir, I believe he is dead." And sure enough he was, to all appearances, and it took some time of hard work to bring him around again. In the meantime, the cook had brought up the saw and placed it on the ground near the table, before I saw him. The saw was rusty and dirty, but it worked very nicely, and I soon had the bone off, the vessels secured, and the wound closed, the whole operation only lasting thirty minutes. We placed the hombre in a tent, and that night we had a hard storm, and the tent blew down. The next morning we pulled him out from under the wet canvas, and he didn't seem to mind it a bit, and wanted some rice. To make a long story short, at the end of ten days all the stitches had been removed, the wound closed, and I sent him off to an island some ten miles distant with some friendly natives, and not long ago he paddled over to see us. Two things of interest may be noted in this case—one, the absence of any pus or infection and the rapid recovery; and the other, the apparent internal explosive effect of high-velocity bullets at short range. The rifle was the Krag-Jörgensen.

ROBT. M. BLANCHARD, M.D.,
A. A. Surg., U. S. Army.

Progress of Medical Science.

Boston Medical and Surgical Journal, November 7, 1901.

Artificial Noses and Ears.—Robert H. Upham prefers vulcanized rubber as the best material to use, and believes that they can be made so perfectly that the wearing of glasses or veils to hide poor workmanship is unnecessary.

On the Establishment of Medicolegal Diplomas.—Wyatt Johnston believes that there is urgent need for some scheme for reforming expert testimony, and that the best standard for the adoption of medicolegal diplomas is that recently accepted in France. This demands a full academic year (nine months), post-graduate study in legal medicine, including practical autopsy work, elementary toxicology, study of nervous diseases, medicolegal methods in examination of stains, questions of sex, etc., and a knowledge of medical law and responsibility. To these requirements should be added at least six months' practical training as assistant in medicolegal work of all candidates, and a practical training in the medicolegal study of disability after injury.

Medical and Sanitary Conditions in the Philippines.—W. P. Chamberlin writes that, though the archipelago lies within 5° and 15° north latitude, the average temperature between the hottest and coldest months ranges from 77° F. to 84° F. The average rainfall is 75 inches. The season of greatest rainfall varies in different parts of the islands, and may be escaped by judiciously moving about. The discomfort from heat is no worse than that which frequently has to be borne in New England. The natives live principally on rice through necessity, as meat is beyond their financial resources. The water supply is from muddy rivers and shallow wells, as a rule. The sewerage and drainage systems, even in Manila, are very incomplete and imperfect, and other towns are innocent of any attempt at sanitation. Much has been accomplished, however, in the way of municipal cleanliness by the Board of Health (composed of Army Medical Officers). Smallpox is everywhere epidemic, and beriberi is common and fatal. Lepers exceed 30,000 in number, and are not, as a rule, segregated. Colentura (a fever in most cases malarial) occurs very frequently among the natives. Malarial fevers are usually of the intermittent type. Pernicious malarial fever is confined to a few localities. In many cases the plasmodium is not found, and Widal's test fails to react. The author believes these belong to a class of fevers, the etiology of which has not yet been ascertained. Dysentery is found in two forms: One due to the *amœba dysenteriæ*, and the other (specific dysentery) to a short rod-like organism, the *bacillus dysenteriæ*. Both are occasioned, it is thought, by polluted water. Venereal diseases occur in 10 per cent. of the sick list among the soldiers. Syphilis occurs less frequently than at the home stations, but chancroidal disease is quite common among the Filipino prostitutes. Parasitic skin diseases prevail to a large extent among the natives. The author believes that the army ration, as used at present, furnishes a good and proper diet.

Journal of the American Medical Association, Nov. 9, 1901.

Typhoid Fever; Dietetic Treatment.—L. Fischer says that the vital points to be considered in the course of treatment of typhoid fever are: 1. Exhaustion from continued draining of the body, if a prolonged diarrhœa exists; thus large quantities of serum are lost, and the blood supply is weakened. 2. Continued fever means continued loss of fat and muscle and rapid emaciation. 3. Loss of strength from recumbent position, and from absence of normal substantial foods. 4. Toxæmia, showing its effect chiefly on the heart and circulating apparatus, demands careful noting when stimulation is demanded. 5. Résumé of foods successfully used in a series of cases of typhoid. 6. The value of saline, and especially the administration of saline infusion per rectum, and if coma prevails, its use by hypodermoclysis. 7. Albumin and salt administered subcutaneously. 8. Peptonization of foods; sterilization

and pasteurization, use of raw milk in this condition. 9. The administration of water with and without carbonic-acid gas. 10. If severe vomiting and gastric disturbance exist, feed per rectum and colon; if severe diarrhœa and tenesmus prevail, feed per stomach.

Treatment of Pneumonia.—De Lancy Rochester believes that the greatest success in the treatment of pneumonia will come from a recognition of its essentially toxic nature. He advocates eliminative and supportive measures, the details of which may be summarized as follows: 1. The sustaining of the metabolic processes of the individual by the administration of easily digested or predigested foods in small quantities at stated intervals, the administration of large amounts of pure water for eliminative purposes, and the administration of oxygen gas by inhalation whenever the absorbing surface of the pulmonary mucosa is involved to such an extent as to interfere with proper metabolic oxygenation. 2. Elimination (*a*) By the liver and bowel through the vigorous use of calomel and salts; (*b*) By the skin through sweats induced by external heat; (*c*) Through withdrawal of blood when indicated by right heart distention. 3. Stimulation of heart by strychnine, alcohol, or ammonium carbonate, and, in suitable cases, by the subcutaneous injection of normal salt solution. 4. The local treatment of the lung by leeching, wet cupping, or dry cupping. He reports 168 cases from hospital and private practice, with a mortality of 10½ per cent. The cases extended over a period of ten years, and represented all walks of life.

Strabismus; Its Treatment.—The conclusions presented by A. E. Davis are: 1. That it is desirable that we have a uniform or standard set of tests for the accurate measurements of strabismus. 2. A better understanding of the physiological action of the ocular muscles and of physiology in general than at present obtains should be had by those treating and operating on strabismus cases. 3. The amblyopia present in most cases of convergent strabismus is functional and acquired, and not congenital, except in rare cases. 4. The non-operative treatment of strabismus—atropine, the occlusion pad, and, in patients old enough, glasses, the stereoscope, and bar-reading—should be begun as soon as the squinting is observed; for, it is in the early cases that this form of treatment is capable of doing so much good. 5. About 30 per cent. of all cases of strabismus may be cured by non-operative treatment alone. 6. Just as soon as the non-operative method of treatment ceases to improve the condition of the squint, it is time to operate. Delay in operating after this is not only useless, but harmful, because the habit of suppressing the image in the squinting eye becomes fixed and the amblyopia worse. 7. After the eyes have been operated on, the use of the stereoscope, bar-reading, the pad, glasses, etc., are of the utmost use in completing the cure. 8. Panas' method of operating for strabismus by stretching the muscles before cutting them is to be recommended as safe in execution, quick in results, and efficient. It should never be performed while the patient's eyes are under the influence of a mydriatic.

New Method of Skiagraphic Diagnosis for Renal and Ureteral Surgery.—G. Kolischer and L. E. Schmidt call attention to the difficulty of representing the ureters on a plate on account of the delicate structure of these tubes. But, by the introduction of a suitable *x*-ray-absorbing material into these organs with a simultaneous skiagraph, results of the highest value may be obtained and diagnostic problems solved that hitherto have been obscure. The technique is as follows: For locating the ureteral openings in the bladder and sounding the ureters in most of the cases, they use Brenner's cystoscope; only in a few cases, where special peculiar conditions prevailed, they resorted to an improved modification of Casper's cystoscope. Extensive cadaver work convinced them that the most desirable material for the sounds is lead, blended with some antimony. This kind of lead wire is extremely flexible, so that the natural course of ureters would not be changed by introducing the sound. These sounds are soft, and their surface is polished up to perfect smoothness, so that injuries to the lining of the renal pelvis and of the ureter are not to be expected, and, in fact, are not to be observed, as careful examination in cadavers has proven. Several excellent skiagraphs illustrate the method described. It is claimed that the latter is free from danger, will determine the course of the ureters, location of renal pelves, diagnose dilatation of the latter, and determine the location of renal calculi. It is possible for the experimenter to determine the seat, and, to a certain extent, the nature of a ureteral obstruction; gallstones can be differentiated from renal stones, and dislocated and enlarged kidneys from non-renal neoplasms.

New York Medical Journal, November 9, 1901.

The Treatment of Cutaneous Epitheliomata.—The conclusions presented by C. W. Allen are: 1. Cutaneous cancer can be treated in all of all histories to preceding local irritation. 2. While other cases may be operative, it is not unreasonable to assume that infection may be one source of irritation occasioning cancer. 3. Benign epithelomatous proliferations of infectious nature transmitted by contagion lend weight to this view. 4. Cancer is curable, but the disease may be allowed to progress until the patient no longer is. 5. No treatment short of the most radical measures should be tolerated. 6. In the application of caustic pastes and subsequent cauterizing dressings we possess a method not alone radical, but one which is in many conditions preferable to the knife. 7. The earlier treatment can be applied, the less likelihood is there of recurrence or of subsequent outbreaks in other parts due to cancerous tissue which has been left behind. 8. The *x*-ray as a means of treatment bids fair to prove quite as effective as caustic applications.

Social Aspects of Dermatology.—The topics discussed by Malcolm Morris in the ninth Lane Lecture are: Fugacious eruptions, erythema, erythema multiforme, dermatitis herpetiformis, pemphigus, erythema nodosum, lupus erythematosus, rosacea, lichen, lichen ruber planus, lichen neuroticus, skin neuroses and mental disturbance, zona, eczema, the unknown pathological factor, the parasitic theory, and the nervous factor. Concerning the last-named disease, Morris' view briefly stated is that in a large proportion of cases eczema is predisposed to by disordered innervation of the skin, and that the diminished resistance thus caused opens the way to the invasion of microorganisms. Some regard eczema as contagious; the lesions certainly are spread on the patient's own skin by auto-inoculation, but the evidence that it can be communicated to another by contagion is very slight. Nurses sometimes have eczema-like-looking eruptions on the hands, when treating children suffering from the disease; but there is a source of fallacy which may easily mislead the unwary in these cases, namely, the impetigo contagiosa not infrequently assumes the appearance of eczema. The inoculation of cultures of the various microorganisms which have been held responsible for the causation of eczema has seemed to me at most to have produced lesions of an eczematoid type, but not the disease which we call eczema.

Devitalized Air; Toxæmia, a Prime Cause of Tuberculosis.—Charles E. Dennison believes that toxæmia arises from stagnant unventilated air existing in the lungs themselves. It is not necessary to show that ventilation, though ample outside the body, may be very deficient within the lungs, because of disuse from insufficient exercise. The force of the argument increases as we go inward with the analysis of the air. The vitiated and fermenting combination of the unrenewed palm marrow air, increased by body heat, the outcoming carbonic acid, and the poisonous tissue detritus, is simply a tenfold intensification of devitalized air outside that body in an unventilated room. The living tissue that will stand this and not deteriorate must indeed be in prime condition. This devitalization, due to lack of ventilation, leads to the pale face, sallow skin, weak pulse, cold hands and feet, and sluggish bowels; the feeble powers of digestion, assimilation, and nerve energy—all of them proofs of flagging vitality. This lethargy is due to enfeebled and poisoned blood-corpuscles, and to a probable self-infection, but especially to deprivation of food for the blood—*i. e.* of oxygen from the air. In addition, the dead air, which marked deficiency of ventilation implies, compels inactivity and limited use of the lungs, and this in turn, means the gradual clogging of out-of-the-way air-cells with the products of combustion. In this manner carbonic-acid poisoning and a species of self-infection are more or less permanently established. The destructive influence of sunlight upon the tubercle bacillus is now generally admitted. If, in addition, the contention of Frankel, that this bacillus is a facultative anaerobic germ, is sustained, then the assertion of a predisposing cause in defective ventilation is strengthened, for the existence of favorable conditions furnished for such germination in the warm unventilated lung.

Medical News, November 9, 1901.

A Case of Raynaud's Disease.—W. A. Haley reports this case. The patient was fifty-five years old. There was an elevation of temperature either from the intensity of the pain or from some other cause. There was fever even before necrosis began. Nature seemed to make an effort to circumscribe the disease, but the process continued to involve new tissue. Within an hour after amputation of the leg, the cut ends of the arteries and veins had lost but little blood. The skin remained cyanotic, the large vessels retained their identity, while the small ones were lost in the tissue, which looked bruised. Blood clots, some of which were organized, were removed

from the long saphenous vein. This disease is not necessarily benign. In this case, heat relieved the pain somewhat, cold made it worse.

Philadelphia Medical Journal, November 9, 1901.

The Ultimate Results of Operation for Cancer of the Uterus.—Charles P. Noble concludes that the majority of patients with cancer of the uterus when they consult the surgeon are too far advanced to warrant the hope of a radical cure. At least 10 per cent. of the cases of cancer of the cervix operated upon remain free from the disease at the end of five years, and may be considered cured. The results of hysterectomy, whether vaginal or abdominal, for cancer of the corpus uteri are far more satisfactory. Abdominal radical hysterectomy for cancer of the uterus, involving the removal of the pelvic glands and the parametria along with the uterus, is still upon trial. Its primary mortality is probably double that of vaginal hysterectomy. The fallacy of the classical teaching concerning climacteric hemorrhages does more than anything else to prevent an early diagnosis of cancer.

Chronic Ulceration of the Stomach Simulating Cancerous Disease; Relation of a Case of Gastroenterostomy with the Murphy Button; Recovery.—James F. W. Ross and E. B. O'Reilly believe that early diagnosis in either chronic ulceration or cancerous disease of the stomach is yet almost impossible. The writers report the case of a woman of twenty-eight years. She was extremely emaciated; there was rigidity of the right rectus muscle, and an indefinite thickening could be felt in the epigastric region. The patient had been suffering for several years with this trouble. At the operation a large growth was found at the pyloric end of the stomach, the perigastric lymphatic glands were enlarged, and the whole stomach wall looked exactly as it does in cases of cancer. The case was thought to be hopeless, so the growth was not removed, but an anastomosis was effected between the stomach and duodenum. A large Murphy button was used. Eleven months later the patient weighed 140 pounds, and looked the picture of health. No mass could be felt, and there were no gastric symptoms.

The Surgery of Pulmonary Abscess; Gangrene and Bronchiectasis Following Pneumonia.—Daniel N. Eisendrath states that both acute and pulmonary abscess and gangrene following pneumonia may develop immediately, and chronic and simple putrid abscesses, with or without bronchiectasis, are more remote sequelæ of both croupous and influenzal pneumonia, especially the latter. The most valuable points in the history are the etiology and the sudden expectoration, after an apparent crisis, of pure non-odorous pus in the simple abscess cases, or of fetid pus in the gangrenous variety. In the chronic cases, there is usually a history of a pneumonia having preceded the condition at some considerable time previously, followed by expectoration of large quantities of pus, with exacerbations of fever, emaciation, often clubbed fingers, etc. Signs of cavity are seldom present. The moist râles, especially of large metallic character, are the most reliable physical signs. The character of the sputum, whether purulent or fetid, is also of great value. Elastic fibers are more often found in gangrene than in abscess. The *x*-ray is only of confirmatory importance. When it shows a shadow at the same point where the physical signs are present, it is of value. The prognosis of abscess and gangrene following pneumonia, medically treated, is not very favorable. Many cases of both varieties can be successfully treated in a surgical manner by pneumotomy.

American Medicine, November 9, 1901.

Appendix Vermiformis Passed in Stool.—W. L. Wallace gives the history of a young man of twenty-one years who had had several attacks of appendicitis. It was finally decided to operate, but twenty-four hours before the time appointed, the patient passed the appendix in a stool. It was three and one-half inches long, and consisted principally of the mucous and submucous coats. It was perforated near the distal extremity and contained several concretions, one of which protruded from the perforation. During the attacks the tumor was in the right inguinal region. The abscess probably broke into the cæcum, carrying the appendix into the head of the colon. This was a very acute appendicitis, with perforation of the appendix, abscess formation, and necrosis of the cæcum, a most dangerous condition which was cured by a fortunate operation of Nature.

The Nature of Internal Lesions in Death from Superficial Burns. John McCrae emphasizes these points: The entire pathological picture presents great similarity to the conditions found in the diseases characterized by the presence of toxins of bacterial origin in the blood. Damage to the lymphatic tissue is a constant feature, but is not necessarily focal, some cases presenting only diffuse degeneration. The patients who live but a few hours after infliction seem more likely to have a focal condition than those who live a longer time, as the condition interpreted as proliferation and phagocytosis is one which may rapidly disappear. The focal lesions are not a true necrosis, but rather a proliferation of the endothelial cells of the reticulum and the capillaries, and a phagocytosis by the leucocytes and endothelial cells, to which latter is due the fragmented, disintegrated appearance which suggests a true necrosis.

The Lancet, November 2, 1901.

Ague Contracted in a Non-Malarious District.—J. L. Stretton narrates the history of a woman with an ague which responded promptly to salicylate of quinine. The attack came on while she was at the seaside, where her brother was also staying. He had lately returned from India. While the patient was at the seaside, she was bitten by some insect on the forehead. It was thought possible by Stretton that the insect might have been itself inoculated by biting the brother (who had had ague in India) and then biting the sister.

Milk or Whey in Enteric Fever.—P. Selby says that milk should not be given as a diet to typhoid-fever patients, first, because milk in many cases forms hard cheesy curds in the stomach. These curds pass along the intestine, giving pain and scraping the raw surfaces of the ulcers, and causing in many cases hemorrhage, perforation, and death. The effect of these cheeselike masses of casein is worse for the patient than feeding on well-masticated solids. Moreover, the perpetual distention of the bowel from the large amount of gases evolved by the digestion or decomposition of the milk keeps the ulcers stretched, and thus thins their floors. Secondly, because the bacillus typhosus breeds rapidly in milk, the more bacteria there are, the more the toxins produced, and the more the toxins the more the fever and constitutional disturbance, with foul mouth, headache, cardiac weakness, delirium, and a feeling of illness. In place of milk he advocates whey made according to the following directions: To each quart of new milk stir in two teaspoonfuls of rennet. Put it into a pan and warm slowly till it curdles. This takes about twenty minutes. Break up the curd and strain the whole through fine muslin. The curd is thus separated from the whey. A quart of milk yields about six ounces of curd. If the whey be sterilized, some lemon juice must be given occasionally to prevent scorbutic symptoms.

Metallic Poisoning.—W. R. Gowers discusses the subject of lead and arsenic poisoning. He calls attention to the fact that there are cases of lead poisoning not presenting any actual paralysis, but an inspection of the mouth will reveal the "lead line," and an omission of this procedure often causes a non-recognition of the true nature of the case. He quotes Jenner's saying that "more mistakes are made many more by not looking than by not knowing." A similar observation applies to the recognition of the pigmentation due to arsenic. The brown pigmentation begins as small spots, which may commence in spots of congestive redness, and the brown tint succeeds the red. These dark spots sometimes exist alone, more often they are seen chiefly on the outer portions of the most pigmented regions, where the tint is more uniform. The uniformity may be due to coalescence of the spots, but sometimes this diffuse coloration seems the first thing. The tint is that which is called sepia, a warm sepia or cold sepia, according to its duration, to use the terms employed by artists. It is not so dark as the pigmentation of Addison's disease, and has not the same distribution. Although it is more marked at places at which there has been pressure, it occurs irrespectively of this, and is greatest on the parts of the trunk least affected in Addison's disease. When the small discrete spots coalesce, they often leave small areas which are unpigmented, and which have a pearly whiteness.

British Medical Journal, November 2, 1901.

A Case of Ulcerative Endocarditis, with Recovery.—H. E. Whitehead and H. W. Syers describe the history of this case. At several stages of the malady it seemed impossible that the patient could recover. Careful nursing, feeding, and use of stimulants had much to do with the recovery, undoubtedly, but they think much of the good result was due to the use of sodium sulphocarbolate. This was ordered in fifteen-grain doses when the patient was at his very worst. Not long after it was given, the patient began to improve. This drug was given every four hours, and was continued until convalescence was established. The writers add that, even if the recovery following the administration of this drug is only a coincidence, it is worthy of notice, and

would emphasize the advisability of the drug being ordered in a similar case.

A Remarkable Case of Aortic Aneurysm of Sixteen Years' Duration; Death from Rupture Externally.—T. R. C. Whipham sums up the remarkable points about this case. For full fifteen years the patient was kept under observation, and during the whole of that time he had a large external tumor, though the aneurysm had been forming for a year, and perhaps longer, before that. The aneurysm passed through frequent and sometimes rapid variations in size, which several times threatened the patient's life. Marked benefit was experienced from prolonged periods of complete rest and treatment, both medicinal and dietetic. During this time the patient had an attack of pleurisy and pneumonia from which he recovered. The entire external part of the aneurysm, which arose from the upper and anterior aspects of the arch, sloughed and came away, after which the patient lived for nearly nine days. The aneurysm then ruptured externally.

A Case of Herpes Zoster Illustrating a Presumptive Cause.—John B. Yeoman reports this case. The patient had an ovarian tumor on the left side removed, after which there were some swelling and uncomfortable sensations in the left lower extremity. Several months later a patch of herpetic vesicles appeared at the level of the third sacral spine, close to the middle line on the left side. Another group appeared on the inner side of the thigh. A few hours after the eruption of the first group, the left labium majus became studded with vesicles. The case ran the usual course, leaving a scarred and pitted surface. The writer believes this to be a case of zoster, the eruption taking place over the cutaneous distribution of the posterior primary divisions of the last dorsal and first lumbar nerves. These nerves are part of the supply of the appendages, and must have been extensively damaged in the operation.

Remarks on a Case of Infantile Scurvy.—John McCaw reports a case of scurvy in a child of ten months, in whom the more prominent symptoms usually seen in scurvy and rickets were absent. No periosteal swelling could be found, the gums were normal in every respect, and two upper and two lower central incisor teeth appeared healthy; there was no proptosis of either eye, nor was there any ecchymosis or œdema of either eyelid. Subcutaneous hemorrhages never took place, and the child never made any complaint of pain on being handled. There was slight beading of the ribs, which was the only distinctive sign of rickets. The child was thought to be vigorous and healthy till he was taken ill. He vomited a considerable quantity of blood, and this was followed by a copious loose motion in which was much altered blood. The child had been fed from birth on condensed milk, and later upon a proprietary food and oat flour. The treatment consisted in the administration of orange juice every two hours, whey and cream at frequent intervals, and one teaspoonful of raw meat juice every four hours. It was advised to apply the icebag to the epigastrium, carefully watching the effect. Eight days later, the child was remarkably improved, and a mixture of arsenic and iron was given, as well as a small quantity of scraped potato or other fresh vegetable in his soup. He was taken to the seaside and made a satisfactory recovery.

Deutsche medicinische Wochenschrift, October 24, 1901.

The Cytodiagnosis of Meningitis.—E. Bendix refers to Widal's observation that in tuberculous-serofibrinous exudates lymphocytes preponderate, while in acute purulent exudations multinuclear neutrophiles occur, as almost the only cellular elements, and gives the results of the investigation of this point in eight cases of meningitis. Of these, five were tuberculous and three sporadic cases of the epidemic form, the diagnosis being confirmed by autopsy. In the former five cases, the fluid obtained by lumbar puncture contained a great excess of small uninuclear cells, while in two of the others the multinuclear neutrophiles were in excess; but the last case, though a meningococcus-intracellularis infection, violated the rule, and showed an excess of lymphocytes.

An External Manœuvre to Facilitate Defecation.—Gumprecht compares the expulsion of a fecal sausage to the delivery of the head in child birth, and describes a measure intended to protect the perineum during the act. It is, however, the region between anus and sacrum, the "posterior perineum," as he calls it, that requires support during the act, and the method is carried out as follows. The left hand is laid over the sacrum with the finger-tips just behind the anus. As the fecal column advances, the soft parts are felt to swell beneath the fingers, and gentle counter pressure is to be made. The fingers then hook themselves around the tip of the coccyx and pry off the first part of the [illegible] out of the anus, and returning to their original position continue to give support during the rest of defecation. The object of the plan is to relieve the pain frequently attending cases of hemorrhoids or slight fissure of the anus, thereby obviating the use of narcotics, and also to reduce the amount of cathartics required, for it will be found that once the first part of the mass is expelled, the rest of the defecation proceeds easily enough.

Uræmic Conditions.—A. Lazarus publishes some results that confirm the recent work of Nolsser and Doering. In experimenting with human serum and rabbits' blood, these authors found that the blood of a uræmic patient reacted in an abnormal way. A certain amount of human serum added to rabbits' blood produces agglutination and hæmolysis of the red cells, owing to the presence of both the "complement" and the "immune" body. The presence of both of these constituents is necessary for the production of hæmolysis, but only the latter is capable of resisting a temperature of 55° C. If, in addition to the amount of active serum required, an additional quantity of serum rendered inactive through the loss of its "complement" by heating is used, in normal cases no change in the reaction is noted, but in the case of blood taken from a uræmic patient the authors found that solution was completely absent. Laqueur repeated these experiments, and found in two cases of uræmia that the same phenomenon occurred, viz., that in this state the inactive serum has the property of abolishing the hæmolytic power of unaltered serum. This peculiarity was not present in any of the other specimens of blood examined, nor even in that of a case of nephritis not giving uræmic symptoms. While it is impossible to draw general conclusions from so limited a number of observations, they may be taken as indicating a decrease in the natural powers of resistance and protection of the blood.

Berliner klinische Wochenschrift, October 21, 1901.

Physostigmine in Paresis of the Intestine.—C. von Noorden has found in this drug a valuable remedy for obstinate tympanites. Five cases are described in which good results followed its application in doses of ½ to ¾ mg. singly or repeated. No unpleasant by-effects are produced and especially in typhoid fever good results are to be looked for.

The Westphal-Piltz Pupillary Phenomenon.—F. Schantz in investigating this phenomenon comes to rather different conclusions from the authors whose name it bears. It consists in a narrowing of the pupil occurring when the orbicularis oculi muscle is forcibly contracted, and has been explained as due to faulty innervation. It is supposed to be of service in differentiating between central and peripheral palsies. Schantz believes, however, that it never is observed except in pupils that are somewhat abnormal, and that its underlying cause is mechanical, and depends on congestion of the iris.

A Case of Subacute Heart Failure with Observations on Cardiac Therapy.—C. A. Ewald describes the case of a man of sixty-two years who, without previous heart symptoms, suddenly went into a state corresponding to a severe lack of compensation, and for two and one-half years continued in a condition of extreme heart failure. At the end of this time, however, the distressing symptoms receded, and he is now both subjectively and objectively as well as ever. There was no indication of exacerbation of a chronic endocarditis, neither did arteriosclerosis seem possible, so that the author regards myocarditis as the cause of the trouble. In discussing the therapy of this difficult case, the author lays stress on the necessity that always exists of relieving the impeded circulation by the removal of any fluid accumulations that may be present before the heart tonics can act to good effect. Morphine is of the greatest value, and the practitioner should never hesitate to give it, as it is one of the most potent remedies at his command. Digitalin and digitoxin have not given the author great satisfaction, and strophanthus also is less useful than digitalis in most cases. The much-dreaded cumulative toxic action of this drug need not be feared, though the fact that its action is always prolonged after its administration has been stopped renders it advisable to interrupt its use from time to time.

Munchener medicinische Wochenschrift, October 22, 1901.

The Future of Surviving Tracheotomized and Intubated Children.—Trumpp has collected data on 351 cases of children operated for diphtheritic stenosis of the larynx between the years 1886 and 1900. Of this number 23 have died, and 328 are still living, though 94 have since the operation developed affections of the pharynx, larynx, or lungs. Although these figures are comparatively

inadequate, still they seem sufficient to controvert Landouzy's assertion that tracheotomy induces a predisposition to tuberculosis. Still, it appears that a certain proportion of those so treated suffer from more or less serious after-effects, and this is true not only of those tracheotomized, but also of those intubated, and it therefore behooves the practitioner not to perform these operations needlessly, but only under urgent necessity.

Gallstones and Cholelithiasis.—Fiedler says that out of 93,000 patients treated at the municipal hospital of Dresden during the last thirty-three years, the diagnosis of gallstones was made 133 times. Of 500 cadavers recently examined, 10 per cent. contained biliary calculi, and of this number 5 per cent. were men and 15 per cent women. In considering the question of diagnosis, the author believes that the most promising field lies in the elaboration of *x*-ray methods, which, he thinks, can be made to give great aid. It is probable that a diseased cystic mucous membrane is of much significance in the production of the stones, though the rôle of bacteria, like the typhoid or colon bacilli, to which importance is being attached, is still rather doubtful. A normal gall-bladder is practically never found, for thickening, contraction, adhesions, erosions, ulcers, cicatrices etc., are nearly always present. No stones larger than about one-half pea-size can traverse the ducts without giving rise to colic, while those larger than a pea cannot escape without causing ulceration. Even if the papilla has been safely reached, at this point a pressure sore is sure to form, owing to the inelastic nature of this opening, and the stone enters the gut by ulceration through the sphincter. In the process of healing, cicatricial contraction takes place, and predisposes to further trouble. The pain of biliary colic has been explained either as due to the actual passage of the offending body or as the result of an attending acute inflammatory process in the gall-bladder. The author believes that both of these possibilities must be taken into account, and that in some cases the one, and in others the other, element predominates. In regard to operative treatment, a conservative attitude should be maintained, and precipitate operation is to be deprecated; but, if the attacks of colic and obstructive symptoms recur, the patient emaciates, and is incapacitated from his employment, while internal medication gives no result, the operation is clearly indicated.

French Journals.

Empyema Cured by One Thoracentesis.—Galliard reports the case of a woman of forty-eight years, who was attacked by a purulent pleurisy during the course of a pneumonia. One puncture was made the seventh day after the beginning of the illness, which resulted in the cure of the pleurisy, while the pneumonia lasted for three weeks. The pint of pus that was evacuated contained an enormous quantity of pneumococci and streptococci.—*Journal des Praticiens*, October 26, 1901.

Action of Milk on the Coagulation of Blood.—Camus observes that intravenous injections of cow's milk in the dog causes a great retardation in the coagulation of the blood. Before trying the experiment, the blood coagulated in twenty-six minutes; after the injection of 28 c.c. of milk into the femoral vein, the blood did not coagulate for four or five hours. The milk of a dog injected into the veins of the same dog caused a retardation in the coagulation.—*Le Progrès Médical*, October 12, 1901.
